Hepatic disease complicating amebiasis usually appears one to three months after an attack of dysentery, but it may manifest itself during an attack or much later. The symptoms of hepatic abscess include pain or discomfort over the liver, with occasional reference to the right shoulder, irregular and intermittent fever, sweats, chills, nausea, vomiting, weakness and loss of weight. Jaundice, except in mild degree, is unusual. Diarrhea or dysentery is present in only about a fourth of the cases of proved liver disease. The diagnosis of hepatic amebiasis depends primarily on a high index of suspicion. Not infrequently a diagnosis of fever of undetermined origin is carried for weeks, because the clinical picture is not specific and the physician does not consider amebiasis as a possible cause of the symptoms. Liver-function studies are not diagnostic, they are merely suggestive and help to point the finger of suspicion at the liver. Leukocytosis of moderate degree is usually present. Stool examination for amebic cysts is, of course, of paramount importance, but is often negative even in the most competent hands. The use of intravenous Diodrast and planography is advocated in attempting to locate a liver abscess. Because of its specificity in amebiasis, emetine constitutes a therapeutic test of great value, but since the drug is a potent protoplasmic poison, it should be used circumspectly.

The following case reports are presented to illustrate the hepatic complications of amebiasis, as well as the extreme difficulty of diagnosis. Because of the obscure nature of the disease it is easy to see how errors in treatment can occur unless one is constantly aware of the possible existence of amebiasis.

CASE 1 R.C.D., a 35-year-old man, was admitted to the hospital, on October 18, 1945, for the treatment of malaria. The significant fact in the history was service in the Southwest Pacific area, during which he had had malaria and amebic dysentery. Prior to this admission he had suffered from diarrhea and pain in the left upper quadrant of the abdomen, accompanied by chills, fever and sweats.

Physical examination on admission revealed the patient to be acutely ill. The only significant finding was marked tenderness and muscle spasm in the left upper quadrant of the abdomen with no definite splenomegaly. The temperature was 102°F., the pulse 100, and the respirations 22. Examination of the blood showed a red-cell count of 4,010,000, with a hemoglobin of 86 per cent (Sahli), and a white-cell count of 13,000, with 81 per cent neutrophils. No malarial parasites were found in the blood smear.

The patient was placed on a regimen of quinacrine, which had no effect on the clinical course — the patient suffered from fever, chills and sweats at irregular periods, with weakness and occasional nausea and vomiting. The tenderness and pain in the left upper quadrant persisted. The red-cell count gradually diminished, and a transfusion of 500 cc of whole blood was given on three occasions. Examination of the stools revealed no amebic cysts or motile forms. Sigmo-
scopic examination was negative. The cephalin-flocculation test was +, and the icterus index was 9 and 3

on two occasions. A gastrointestinal x-ray series was negative. A sense of fullness developed in the epigastrium, together with slight enlargement of the liver. At the same time the patient's sense of well being gradually improved, and the pain in the left upper quadrant of the abdomen slowly subsided. No splenomegaly could definitely be made out at any time.

On November 21 a definite tender mass about the size of a lemon was noted in the left upper abdominal quadrant. Surgical exploration disclosed an encapsulated abscess in the region of the anterior surface of the left lobe of the liver. The abscess was incised freeing "anchovy-paste" pus, drained by suction, packed and irrigated daily with 1:1000 solution of emetine hydrochloride. At the same time 20 mg. of emetine hydrochloride was administered intramuscularly three times a day for 7 days.

On November 25 while the patient's condition was slowly improving he developed a chill, followed by a rise in temperature to 103.4°F. A blood smear revealed the presence of *Plasmodium vivax*. Response to quinacrine hydrochloride was prompt and convalescence continued uneventfully. The patient made a complete recovery.

In the early stages of the illness the patient's chief complaint was directed entirely toward the left upper quadrant. The consistently negative blood smears and the failure to respond to quinacrine on admission removed malaria from the list of diagnostic possibilities, although this disease had appeared to be the likeliest cause of the chills and fever. Subsequently, intensive studies made to rule out the presence of blood-stream infection and renal suppuration were negative. The possibility of amebiasis had been entertained, but no definite findings were noted. In retrospect, we believe that the use of emetine early in the course of hospitalization would have been of significant diagnostic value, and might conceivably have prevented the formation of a full-blown liver abscess. Despite the failure to find the pathogen in the feces, the pus or the wall of the abscess, it was considered certain, on clinical grounds, that the patient did have an amebic abscess. The pus was characteristically free of pathogens, although they are often found in the wall of the abscess.

CASE 2 W.F.B., a 27-year-old farmer, had been discharged from the Army on January 20, 1946, shortly after his return from the Southwest Pacific. At the time of discharge he was in good health. He had never been ill during his service in the Army and did not recall any minor episodes of diarrhea or fever. About 3 weeks prior to admission to the hospital he became ill, with fever and pain in the right chest. He consulted his family physician, who treated him for malaria without improvement and who, about 10 days before admission, thought that there was fluid in the right chest. No x-ray film was taken, nor was a thoracentesis performed. On admission the patient complained of mild pain in the lower right chest on deep inspiration, as well as a slight cough without expectoration. There had been no dyspnea. He had lost 15 pounds in the preceding 2 weeks. He had had frequent head colds for several years. Several chest x-ray films taken in the Army had been negative for tuberculosis. He had had no significant illness or operations.

Examination revealed a well developed and well nourished man, who was ambulant and not acutely ill. Significant findings were slight impairment of percussion resonance over the extreme right base of the chest posteriorly, distant breath sounds in the same area and occasional superficial fine rales. No friction rub could be heard. The liver edge, which was palpable on deep inspiration just under the right costal margin, was somewhat tender. Heavy fist percussion over the liver elicited pain. The temperature was 100°F., the pulse 88, and the respirations 18.

Examination of the blood disclosed a normal red-cell count and hemoglobin, with a white-cell count of 15,900 and a normal differential. No malarial parasites were found in the smear. Urinalysis showed a few white cells per high-power field. The sedimentation rate was 3 mm in 1 hour. Repeated sputum specimens were negative for tubercle bacilli. An intradermal tuberculin test was positive. Stool examinations for ova and parasites were negative. Blood agglutination tests for typhoid, paratyphoid A and B, undulant and typhus fevers were negative. A prostatic smear revealed a few pus and epithelial cells but no bacteria.

A roentgenogram of the chest taken on February 25 showed obliteration of the right costophrenic angle probably due to fluid, the lung fields were clear. Examination was repeated on March 20, when the diaphragms were smooth in contour and the costophrenic angles were clear. Another roentgenogram, taken on April 6, disclosed clear lung fields but abnormal elevation of the right dome of the diaphragm. Intravenous and retrograde pyelography revealed no abnormalities.

The patient ran an irregular, febrile course, the temperature ranging from 98 to 102°F almost daily. There was no response to penicillin and sulfadiazine. For 6 days, 65 mg of emetine hydrochloride was administered intramuscularly every day, concomitantly with oral administration of Diodoquin. Within 24 hours the temperature became normal and remained so. The patient began to regain his lost weight and soon recovered his former sense of well being. The hepatic tenderness also subsided, and the liver edge was no longer palpable. At no time was any abnormality noted on sigmoidoscopic examination.

Despite the normal sigmoidoscopic findings and the failure to demonstrate *E. histolytica* in the stools, the dramatic response to emetine and Diodoquin leaves little doubt that this patient had a liver abscess due to amebic infection. It is not unusual for hepatic abscesses to incite diaphragmatitis, pleuritis and pleural effusion, and this chain of events is considered to have occurred in this case. So far as could be determined, the hepatic abscess subsided. Further observation is warranted, however, since relapses may occur, necessitating surgical drainage.

CASE 3 U W, a 25-year-old Negro veteran of the North Burma campaign, had been discharged from the Army because of accumulated points on September 1, 1945. His health as a civilian had been good, and he had never been ill while in the service. On the day of discharge he suddenly developed severe, cramping pain in the upper abdomen, with nausea and vomiting, the stools were normal. The symptoms became progressively worse, and on September 7 he was admitted to the hospital.

On physical examination the patient was acutely ill and appeared to be in severe pain, rolling and tossing in bed. He lay with the knees flexed on the abdomen. He was perspiring freely. There was rigidity of the abdominal muscles in the upper half of the abdomen, with marked tenderness. On palpation there was a sensation of fullness in the upper abdomen. The lower abdomen was soft, no jaundice was noted. Rectal examination was negative. The temperature was 99.2°F, the pulse 100, and the respirations 20. Examination of the blood disclosed a red-cell count of 2,050,000, with a hemoglobin of 59 per cent (Sahli), and a white-cell count of 20,950, with 80 per cent neutrophils. The prothrombin time was 25 seconds (normal, 18 seconds). The total serum protein was 8.7 gm per 100 cc, with an albumin of 3.0 and a globulin of 5.7 gm. The cephalin-flocculation test was ++++. The icterus index was 5.7. A bromsulphalein test showed 10 per cent retention of the dye at 45 minutes and 5 per cent at 60 minutes. A blood smear for malaria was negative. A roentgenogram of the abdomen was negative, as was a urinalysis.

It was thought by the surgeon that an exploratory laparotomy should be done because of the possibility of a perforated duodenal ulcer. Operation disclosed an enlarged liver of firm consistence, with fine nodules on its surface. The postoperative course was uneventful except for fever and

nausea. On September 22 the patient developed diarrhea and examination of the stool showed *E. histolytica*. He was placed on emetine hydrochloride, carbarsone and later Diodoquin, with prompt subsidence of the temperature and symptoms. On October 14, during convalescence, he suddenly developed chills and fever. A blood smear was positive for *P. vivax*. The white-cell count was 5600, with 60 per cent neutrophils. Quinacrine obtained prompt and satisfactory results. The patient left the hospital on October 28, fully recovered.

The pathological report was as follows:

Histologic examination reveals a section of liver whose portal canals are infiltrated with numerous inflammatory cells, mostly round cells. Some of these are plasma cells. There is a scattering of eosinophils. Free hemorrhage is noted in the interstitial tissue. There is early connective tissue replacement, with early cirrhotic changes. No specific organism is noted in the section. There are no parasitic ova. There are some attempts at biliary regeneration. Diagnosis: hepatitis, with early cirrhotic changes.

If the possibility of amebic hepatitis had been seriously considered in this case, it is likely that surgical intervention could have been avoided. At this stage, treatment with emetine is effective and often prevents the development of large liver abscesses requiring surgical drainage. It is interesting to note that there was a well marked leukocytosis, as well as a clinical picture of an acute surgical abdomen. Even if one is aware of the possibility of acute amebic hepatitis, it is difficult to see how surgery can be withheld in some cases of this type. The therapeutic test of emetine, if time permits, is a prompt help in diagnosis. Another point of interest in this case was the absence of jaundice, despite the diffuse hepatitis.

CASE 4 V B, a 34-year-old man, was admitted to the hospital on November 22, 1945. Five weeks previously, while returning from the Southwest Pacific, he had developed abdominal cramps and diarrhea, with blood and mucus in the stools. Two days before admission these symptoms recurred. The diarrhea soon became less marked, but anorexia and pain over the liver set in. There was no nausea or vomiting. No other significant facts were uncovered in the history.

Physical examination revealed a moderately ill but well developed and well nourished man. The abdomen was soft, flat and not tender. On deep inspiration the edge of the liver was palpable and tender. No jaundice was present. The temperature was 102.6°F and the pulse 86. The blood pressure was 130/90. A clinical diagnosis of amebic dysentery and hepatitis was made.

Examination of the blood showed a hemoglobin of 96 per cent (Sahli) and a white-cell count of 18,100, with 83 per cent neutrophils, of which 15 per cent were nonsegmented forms. No malarial parasites were seen in a thick blood smear. The cephalin-flocculation test was +++, and the icterus index 5. On November 23 trophozoites of *E. histolytica* were identified in a stool specimen.

The temperature was remittent, reaching 104.4°F. 2 days after admission emetine therapy was instituted on November 23 and continued in a daily dosage of 65 mg intramuscularly for 7 days. Diodoquin was subsequently administered for 3 weeks. The temperature subsided and reached a normal level on December 1, after which it remained normal. Symptomatic improvement was quite marked by November 28.

The patient made an uneventful recovery and was discharged from the hospital on January 17, 1946. Prior to discharge laboratory studies were repeated and revealed a normal white-cell count and differential. The cephalin-flocculation test was ++, and the bromsulphalein-retention test was normal. The icterus index was 5.8. A chest x-ray film was normal. Stool studies disclosed no pathogenic organisms.

This case provides an example of prompt diagnosis and early institution of treatment. The results were gratifying in that shortly after institution of therapy the patient showed marked improvement and proceeded to an uneventful recovery. This case illustrates the concomitance of amebic dysentery and hepatitis, probably in the preabscess stage. The early diagnosis was of course aided by the presence of diarrhea and the finding of the motile vegetative form of *E. histolytica* in the stool.

SUMMARY

Amebiasis constitutes a challenge not only to the medical profession at large but also to the physicians of the Veterans Administration. Because of the bizarre symptomatology, the diagnosis of amebiasis is beset with many difficulties and pitfalls. The great number of potential carriers of *Endamoeba histolytica* makes the problem one of immediate importance. It is imperative that physicians be

acquainted with the problem of amebiasis and be constantly on the alert to make the diagnosis early. Prompt therapy is the only method of preventing the serious and sometimes fatal complications of the disease.

Four cases of amebiasis with hepatic complications are presented, with a view to emphasizing the difficulties of diagnosis. It is anticipated that such cases will become more frequent within the next few years.

CLINICAL NOTE

FRIEDLANDER-BACILLUS MENINGITIS TREATED WITH STREPTOMYCIN*

S. TARTAKOFF, M.D.,† BRUCE GRYNBAUM, M.D.,‡
AND PHILIP M. LE COMPTE, M.D.§

WEST ROXBURY, MASSACHUSETTS

INTEREST in the treatment of local and general infections caused by organisms ordinarily resistant to the usual antibiotics has become increasingly stimulated by recognition of the fact that within recent years isolated cases have been reported in which successful results were obtained. In 1943 Ransmeier and Major¹ reported a case of septicemia associated with Friedländer-bacillus meningitis and published the report after an analysis of 29 cases of similar type that had been collected from the literature. In the 30 cases reported so far, 3 patients recovered, 2 with the use of the sulfonamides and 1 following operative evacuation of an abscess.

More,² in 1943, reported a case of meningitis due to a Friedländer bacillus in a twenty-six-month-old infant, with recovery following sulfonamide therapy.

In February, 1945, the favorable effects of streptomycin in experimental infections with micro-organ-

isms of the Friedländer group were reported.³ In November of the same year Herrell and Nichols⁴ discussed the clinical use of streptomycin in a study of 45 cases in which bronchiectatic involvement by the Friedländer bacillus was treated by aerosol and intramuscular injection of streptomycin.

It is apparent that, although streptomycin is being employed with increasing frequency, experience with the drug is limited. In the following case a patient with recognized meningitis due to Friedländer bacillus Type B was treated by intravenous and intrathecal injections of streptomycin. The clinical findings indicated an unmistakable, overwhelming meningitis, but evidence of such an infection was entirely absent grossly and almost so microscopically at the time of death.

CASE REPORT

F. M., a 49-year-old married man, was admitted to the hospital on July 30, 1945, with a diagnosis of a right-frontal brain tumor.

The past history indicated that he had not felt vigorous for 25 years. Seven years before admission he had been hospitalized for 8 months at the Veterans Administration Facility at Rutland Heights, Massachusetts, because of tuberculosis but no evidence of activity had been found. About 4 years later he began to have right-sided headache and difficulty in vision involving the right eye and to experience pins-and-needles sensations in the left hand and arm. Two and a half years before admission he had had a spell of unconsciousness during the night, and the spells had recurred at intervals of about 3 months until 5 weeks before admission, since then there had been three seizures. An aura, in the form of restlessness, was experienced preceding the convulsions. On one occasion there had been urinary incontinence. In 1944 the patient had been hospitalized at the Soldiers' Home in Chelsea, Massachusetts, at the Veterans Administration Facility, Bronx, New York, and at the Boston City Hospital. During 1945 he had been at the Veterans Administration Facility at Mt. Alto Washington, D. C., and at the Veterans Administration Facility, Rutland Heights, Massachusetts. During these earlier periods of hospitalization two encephalograms and a ventriculogram had been done.

*From the Veterans Hospital West Roxbury, Massachusetts. Published with the permission of the Chief Medical Director, Department of Medicine and Surgery, Veterans Administration, who assumes no responsibility for the opinions expressed or the conclusions drawn by the authors.

†Chief Neurological Service, Veterans Hospital West Roxbury.

‡Physician, Veterans Hospital West Roxbury.

§Formerly consultant in pathology, Veterans Hospital West Roxbury.

On admission the patient complained of head pain and of difficulty in co-ordination of the eyes and hands. He had a feeling as though his head were being pulled to the right and backward. He was conscious of difficulty in memory and cerebrated more slowly than usual. He had also been conscious of increasing irritability during the preceding 2 months.

Physical examination showed a well developed and well nourished man 71½ inches tall and weighing 151 pounds. Two ventriculographic buttons were palpable in the skull. There was uncertainty in gait. The head intermittently and involuntarily twisted, the chin turning to the left and the occiput far to the right. There was considerable rhythmic tremor of the musculature, particularly about the shoulder muscles. The eye pupils, fields and fundi were normal. The breath sounds were harsh, but the heart sounds were normal. The pulse was 76, and the blood pressure was 124/80. Examination of the abdomen and extremities was negative, and the reflexes were physiologic.

Prior to operation the blood Wassermann and Mazzini reactions were negative. The hemoglobin was 16.9 gm and the white-cell count was 7100. Urinalysis was negative for sugar, albumin and organized pathologic elements. The sedimentation rate was 15 mm in 1 hour. The coagulation time was 3¼ minutes, and the bleeding time 1¼ minutes.

X-ray study on August 2 disclosed that the apex of the right lung was obscured. There was evidence of fibrosis and calcification above the level of the 2nd rib anteriorly, most marked in the extreme apex. These changes suggested parenchymal infiltration, apparently of long duration, with no evidence of recent changes. The remainder of the lung field was clear, with no changes in the cardiac silhouette. There was a slight bulge of the aortic knob. The changes in the right upper lung were suggestive of a tuberculous process. X-ray examination of the skull revealed areas with a somewhat circular appearance on both sides of the median line, apparently in the occipital region. It was impossible to state whether or not these findings were due to trephining or to bone erosion. No other abnormalities worthy of note could be made out. There was no indication of any definite lesion. The blood-vessel markings and the sutures disclosed no variations.

On August 13 a ventriculogram showed absence of filling of the anterior horn of the right ventricle. There was slight displacement of the ventricular system to the left.

On that day a craniotomy was performed by Dr. Gilbert Horrax and his associates, and a meningioma was removed from the right hemisphere in the frontal area. On the following morning the pulse, which had been under 90, had climbed to 120, the temperature was 102.2 and, later that day, 103.2° F, and the respirations were 35 per minute. From that time on until the time of death the patient ran a spiking febrile course, the temperature receding to normal only on August 18, and for the most part spiking to 103° F. The pulse and respiration were proportionately elevated. On the 3rd hospital day the patient complained of soreness on swallowing. Three days later he complained of a sore throat and a small grayish membrane was observed in the right tonsillar fossa. A throat culture was reported as showing the following organisms: gram-positive, lancet-shaped diplococci, with the appearance of pneumococci, short-chain, nonhemolytic streptococci, staphylococci, and gram-negative, encapsulated diplobacilli, with the appearance of Friedländer bacilli.

On August 20 lumbar puncture was done and 15 cc of xanthochromic fluid was removed under pressure. On the following day the patient was noted to be less alert, he was hypersensitive to touch and less rational. On that day 20 cc of definitely cloudy fluid was removed that contained 100 white cells and 5 red cells per cubic millimeter and had a sugar content of 16 mg and a protein content of 136 mg per 100 cc. A blood culture showed Friedländer's bacillus Type B, which was also demonstrated on spinal-fluid culture 2 days later. A definite diagnosis of meningitis was made and penicillin in doses of 20,000 units was given intramuscularly every 3 hours, as well as two intrathecal injections of penicillin, each containing 15,000 units. The patient received continued intramuscular and intrathecal penicillin, supplemented by 1 gm of sulfadiazine every 4 hours, through August 26. By that time he had become increasingly ill and markedly confused and disoriented and had developed paralytic ileus.

A spinal-fluid culture on August 24 eventually showed no growth. While the results of the culture were being awaited, however, the patient's condition became progressively worse, and it was believed that he could not possibly survive unless some heroic measures were instituted.

On the night of August 26 a dose of 0.05 gm of streptomycin was injected intracisternally at 10:00. At midnight 1.0 gm of streptomycin in 1000 cc of physiologic saline solution was given intravenously, and the same dose was repeated every 8 hours. Intracisternal injections of 0.05 gm of streptomycin were again given on August 27 and August 28. The spinal fluid, which on August 25 had become gelatinous to the point where only drops could be obtained even by suction, became less viscid. His condition seemed to be unchanged until the morning of August 29, when the patient's color suddenly became poor, the pulse more rapid and the respiration somewhat labored. Approximately 2 hours later he suddenly became pulseless and slightly cyanotic and within a few minutes stopped breathing. He was pronounced dead at 11:15 a.m.

Autopsy. At post-mortem examination, performed on August 29, the significant findings were confined to the lungs and brain. The immediate cause of death was represented by small coiled emboli in the branches of both pulmonary arteries. Although the source of these clots was not identified, it was assumed that they came from the small veins of the leg. The apex of the right lung was occupied by an extensive old dense scar. In the upper part of the right lower lobe there was a group of small abscess cavities averaging about 1 cm in diameter and having ragged walls and purulent contents. Adjacent to these cavities the parenchyma of the lung had a tough, grayish-yellow appearance, suggesting an organized pneumonia. The left lung was essentially normal, except for the emboli and some emphysematous blebs.

Microscopically, the right apex showed old dense collagenous tissue, with anthracotic pigment and a few surviving alveoli lined by cuboidal cells and containing phagocytes with foamy cytoplasm. There was also much peribronchial fibrosis, with scattered lymphocytes. The walls of the abscesses were fairly dense and fibrous, the exudate within them showing striking evidence of healing, with a predominance of large macrophages having a finely vacuolated cytoplasm (Fig. 1). There were also a few lymphocytes, plasma cells

FIGURE 1 Photomicrograph of Wall of Pulmonary Abscess (phosphotungstic acid-hematoxylin — $\times 400$)

The exudate is composed largely of phagocytes, with foamy cytoplasm, and a few lymphocytes and polymorphonuclear leukocytes.

and polymorphonuclear leukocytes. Careful examination of sections stained by Giemsa's method revealed no bacteria. In the area of the abscesses there was an organizing pneumonia with a similar type of exudate.

The operative wound in the brain appeared clean, and the leptomeninges of both brain and spinal cord were grossly thin and delicate. Microscopically, however, there was the picture of a healing meningitis. The meninges showed an apparently edematous fibrillar connective tissue, scattered through which there were relatively scarce cells, most of which ap-

peared to be large mononuclear cells or monocytes, many of them having indented nuclei and pink-staining cytoplasm without definite evidence of phagocytosis (Fig. 2), there

FIGURE 2 Photomicrograph of Meninges (hematoxylin and eosin — $\times 400$)

Note the scattered mononuclear cells

were also a few lymphocytes. There was no acute polymorphonuclear reaction, and no bacteria were seen in the Giemsa-stained sections. The brain tissue appeared normal. Sections of the dura showed an organizing blood clot with a few polymorphonuclear leukocytes but no bacteria. There was some amorphous bluish-staining material suggesting fibrin foam. Unfortunately, the results of culture were not available.

The anatomical diagnoses were as follows: wound of recent operation (craniotomy for removal of meningioma), healing meningitis, pulmonary apical scars, healing pulmonary abscesses and resolving pneumonia (right lower lobe), pulmonary emboli (bilateral), and hydrothorax (bilateral).

DISCUSSION

On August 21 and again on August 23, Friedländer bacilli were cultured from the spinal fluid in this

case. In spite of the fact that spinal-fluid culture on August 24 showed no organisms, the facts remain that the spinal fluid became increasingly gelatinous subsequent to that day and that the patient's clinical progress was increasingly unsatisfactory. It is significant that after the administration of streptomycin the spinal fluid became less viscid and that at autopsy careful study of the meninges and of the surface of the brain disclosed evidence of a nearly healed meningitis. Whether such a finding might have presented itself with the continued use of penicillin alone is a question that cannot be answered. The complete disappearance of the extreme viscosity of the spinal fluid is regarded as having been due to the effect of streptomycin. It must be conceded that the absence of gelatinous accumulation and of any viscid accumulation was a surprising and dramatic finding. It may fairly be stated that this man did not die of a Friedländer-bacillus meningitis. His death was due to pulmonary embolism incident to a thrombophlebitis occurring in his lower extremities during the course of his illness.

SUMMARY

A case of Friedländer-bacillus meningitis treated with streptomycin administered intravenously and intrathecally is presented. The spinal-fluid changes during treatment and the complete absence of gross and the nearly complete absence of microscopical evidence of meningitis at autopsy are stressed.

Correction. Several errors appear in the paper "Clinical Malnutrition in Italy in 1945" by Drs. Metcalf and McQueeney, which appeared in the September 26 issue of the *Journal*. In Table 2, under the heading "Anemia," both the third and fourth percentage figures should be changed from "43" and "57" respectively to "16," and in the second footnote, the number of cases should be changed from "70" to "258." In Table 3, under the same heading, the sixth percentage figure should be changed from "64" to "18.8," and in the second footnote, the second sentence should read, "Determinations made in 942 cases of the total population."

MEDICAL PROGRESS

OTOLARYNGOLOGY

CARLYLE G FLAKE, M D *

BOSTON

THE following summarized articles, which appeared in the literature on otolaryngology during 1945, were selected as being of general interest

THE EAR

Fenestration Operation

Fenestration of the labyrinth for the purpose of providing better hearing in otosclerosis is now a well established and widely performed operative procedure. Although many advances have been made in the technic of operation and the proper selection of patients, closure of the fistula by the formation of new bone remains the current post-operative bugbear.

With the latest modification in his technic, Lempert¹ believes that he has solved the two major causes of previous failure—osteogenic closure of the newly created vestibular fenestra and damage to the organ of Corti by postoperative serous labyrinthitis. The modification consists of placing a cartilage stopple in the fenestra, the cartilage, which is obtained from the spina helix, is regarded as ideal for the purpose, since it is smooth, inert and nonirritating to the endolymph and yet hard and tough enough to block osteogenesis in the bony rim of the freshly cut window and sufficiently light and elastic to transmit sound impulses efficiently. Fifty patients selected because of satisfactory evidence of good cochlear-nerve function were operated on, so that operative success and failure alike could, with fairness, be traced solely to the operation itself. The results were reported as 100 per cent successful. Partial or total closure of the fenestra had occurred in 140 of the 1000 patients operated on by Lempert during the previous seven years. Eighty-eight of these closures took place in the first 300 cases, in which fenestration was done in the prominence of the external semicircular canal. In the last 700 cases, in which the fenestra was made in the surgical dome of the vestibule, fifty-two closures occurred.

Day² reports that the operation is extremely difficult and tedious, usually requiring two and a half to three and a half hours. Moreover, the procedure is not bloodless, painless or devoid of danger. Since it is a purely mechanical method to create a new pathway for the transmission of sound waves to the

cochlear end organ, it does nothing toward removing or eliminating the otosclerotic foci and does not restore lost nerve function. Despite many failures, however, brilliant results have been achieved in restoring practical conversational hearing to an increasingly large number of persons with otosclerotic deafness. An analysis of the results of the operation in cases submitted to the Otosclerosis Study Group reveals that in 211 cases in which the original operation, which involved the horizontal semicircular canal, was performed, improved hearing followed in only 47 per cent, and hearing reached a satisfactory level of understanding of normal speech in only 10 per cent. With the revised operation, in which the window is created in the roof of the vestibule, 76 per cent of 554 patients had improved hearing, but in only 31 per cent did the hearing reach the practical level. The only justifiable purpose for the operation is to restore practical conversational hearing, and cases reported as successful should be limited to those in which the hearing reaches this level. The practical level of hearing for normal conversation is somewhere around the level of 25 decibels. Therefore, if a patient has a loss of 70 decibels and the operation gives him a 30-decibel improvement, he is still unable to understand normal speech and the operation should not be considered successful. Not more than 10 per cent of patients with otosclerosis are considered suitable for the operation, which should be reserved mainly for adolescents and young adults. Patients over forty years of age usually have secondary nerve degeneration that prevents their hearing from reaching a practical level after operation. Good bone conduction is regarded as essential, since hearing loss by bone conduction indicates nerve damage and cannot be restored by operation. A hearing aid is preferable to operation in cases in which a high postoperative hearing level cannot reasonably be expected to result. In Day's series of 75 cases, a good result with practical hearing for conversation was obtained in 40, or 74 per cent, of 54 patients operated on between October, 1941, and June, 1944. In 3 cases the fenestra closed but was successfully reopened, making a total of 43, or 80 per cent, with successful results. Average hearing loss for the speech range for pure tones before operation was 48.2 decibels. Following operation, there was an average improvement of 28.5 decibels and an average hearing loss in the speech range of 19.7 decibels.

*Surgeon in otolaryngology, Children's Hospital; otolaryngological surgeon, Peter Bent Brigham Hospital, assistant in laryngology, Harvard Medical School.

The conclusion was reached by Berry³ that a well fitted hearing aid could give greater sound amplification and furnish help to a wider group of patients at the cost of less pain and worry than could a fenestration operation. On the premise that hearing for speech is more important than hearing for pure tones, as measured by standard audiometers, Shambaugh⁴ retested Berry's conclusions and surveyed a group of patients on whom the fenestration operation had been performed after the use of hearing aids, to get their impression of the comparative benefits. The testimony was predominantly in favor of the operative result. According to Shambaugh, the hearing aid shows to best advantage under standard test conditions—that is, in a soundproof room in which there is little interference of static, distortion and amplification of outside noises, all of which combine to hamper the hearing for speech. So that subjective impressions might be ruled out, 14 patients, each of whom had worn a hearing aid before operation and had been tested by means of a speech audiometer, with and without the aid, both before and after fenestration operation, served as the basis for the following conclusion: patients with an average gain (20 decibels or more with the pure-tone audiometer) in hearing after the fenestration operation had better hearing for speech than they had with hearing aids before operation, and those who obtained less than the average gain in hearing for pure tones were not benefited. On the basis of one-year results with the fenestration operation as it is now used, the further conclusion is reached that the ideal subject for the fenestration procedure has about a 90 per cent chance of securing permanently better hearing and a 70 per cent chance that the hearing will be as good as, or better than, it was with a hearing aid.

Congenital Deaf-Mutism

Carruthers⁵ reports that in Australia, especially during the years 1940, 1941 and 1942, an exanthematous disease, believed to be rubella, occurred in widely scattered parts of the country. There was a greater tendency than usual for adults, and especially young adults, to contract the disease. A proportion of pregnant women had this disease, which, although minor for the mother, had disastrous effects on the developing fetus, as revealed at birth. Congenital cataracts, cardiac defects and anomalies, deaf-mutism, microcephaly, general stunting of the growth and dental defects were reported. The stage of pregnancy at which the infection occurred was apparently most important in influencing the type and extent of congenital defects. If infection occurred during the first six weeks, fetal damage was widespread, including the eyes, both divisions of the ears, the heart and perhaps many other organs. After the sixth week the eyes sometimes escaped, the heart was spared and the semicircular canals developed normally, but the

cochlea was still likely to be damaged and growth was sometimes retarded. After the third month damage to the fetus was rare. Apparently there was no correlation between the severity of the infection in the mother and the degree of fetal damage. Since deafness is often not discovered until it is evident that speech development is retarded, it is not yet possible to state exactly what proportion of children born of mothers who had rubella during pregnancy have severe hearing defects, although it is likely that the figure is over 50 per cent. Of 102 children with congenital defects whose mothers were known to have had rubella during pregnancy, 74 were deaf and 14 of these also had congenital heart lesions. The most frequent type of congenital anomaly in deaf-mutism is that in which the middle ear and the bony form of the inner ear are normal and the vestibule and semicircular canals are more or less normal in development but in which the cochlea, especially Corti's organ, and the saccule show evidence of maldevelopment. Congenitally deaf-mute infants whose deficiency is the result of maternal rubella belong to this group, for these patients are quite deaf but not completely insensitive to sound and, so far as they have been tested, give evidence of an active, although reduced, vestibular apparatus. Many children gave evidence of loss of hearing over the tone range 512 to 2048. Tests of caloric labyrinthine reactions in 9 cases showed slightly reduced responses as compared to normal. An interesting feature of the test was absence of sickness from caloric stimulation, even when a pronounced nystagmus was induced. By contrast with the gross inactivity of the cochlea, it is obvious that often the semicircular canals were largely spared. In the series of Carruthers 17 deaf-mute children were under observation, the oldest of whom was six and a half and the youngest three and a half years. At the age of three and a half years several children began to use their hearing. It is hardly possible that the receptive function of the inner ear actually developed, rather, it is believed that the children began to take some interest in their residual powers as a result of mental growth and training. Parents are instructed to use every means to preserve the baby voice until such a time as special training is practicable.

Pregnancy and Otosclerosis

Allen,⁶ in a review of the literature regarding the possible etiology of otosclerosis, discussed the effects of pregnancy on deafness, as observed in 18 cases without audiograms, including 13 by personal communication and 5 from the literature, and 54 cases with audiograms, including 19 by personal communication and 35 from the literature. No change in hearing occurred in 24 cases without and in 8 with audiograms. The otologists believed that decrease in hearing was consistent with that which

MEDICAL PROGRESS

OTOLARYNGOLOGY

CARLYLE G. FLAKE, M.D.*

BOSTON

THE following summarized articles, which appeared in the literature on otolaryngology during 1945, were selected as being of general interest.

THE EAR

Fenestration Operation

Fenestration of the labyrinth for the purpose of providing better hearing in otosclerosis is now a well established and widely performed operative procedure. Although many advances have been made in the technic of operation and the proper selection of patients, closure of the fistula by the formation of new bone remains the current postoperative bugbear.

With the latest modification in his technic, Lempert¹ believes that he has solved the two major causes of previous failure—osteogenic closure of the newly created vestibular fenestra and damage to the organ of Corti by postoperative serous labyrinthitis. The modification consists of placing a cartilage stopple in the fenestra; the cartilage, which is obtained from the spina helcis, is regarded as ideal for the purpose, since it is smooth, inert and nonirritating to the endolymph and yet hard and tough enough to block osteogenesis in the bony rim of the freshly cut window and sufficiently light and elastic to transmit sound impulses efficiently. Fifty patients selected because of satisfactory evidence of good cochlear-nerve function were operated on, so that operative success and failure alike could, with fairness, be traced solely to the operation itself. The results were reported as 100 per cent successful. Partial or total closure of the fenestra had occurred in 140 of the 1000 patients operated on by Lempert during the previous seven years. Eighty-eight of these closures took place in the first 500 cases, in which fenestration was done in the prominence of the external semicircular canal. In the last 700 cases in which the fenestra was made in the surgical dome of the vestibule, fifty-two closures occurred.

Day² reports that the operation is extremely difficult and tedious, usually requiring two and a half to three and a half hours. Moreover, the procedure is not bloodless, painless or devoid of danger. Since it is a purely mechanical method to create a new pathway for the transmission of sound waves to the

cochlear end organ, it does nothing toward removing or eliminating the otosclerotic foci and does not restore lost nerve function. Despite many failures, however, brilliant results have been achieved in restoring practical conversational hearing to an increasingly large number of persons with otosclerotic deafness. An analysis of the results of the operation in cases submitted to the Otosclerosis Study Group reveals that in 211 cases in which the original operation, which involved the horizontal semicircular canal, was performed, improved hearing followed in only 47 per cent, and hearing reached a satisfactory level of understanding of normal speech in only 10 per cent. With the revised operation, in which the window is created in the roof of the vestibule, 76 per cent of 554 patients had improved hearing, but in only 31 per cent did the hearing reach the practical level. The only justifiable purpose for the operation is to restore practical conversational hearing, and cases reported as successful should be limited to those in which the hearing reaches this level. The practical level of hearing for normal conversation is somewhere around the level of 35 decibels. Therefore, if a patient has a loss of 70 decibels and the operation gives him a 35-decibel improvement, he is still unable to understand normal speech and the operation should not be considered successful. Not more than 10 per cent of patients with otosclerosis are considered suitable for the operation, which should be reserved mainly for adolescents and young adults. Patients over forty years of age usually have secondary nerve degeneration that prevents their hearing from reaching a practical level after operation. Good bone conduction is regarded as essential, since hearing loss by bone conduction indicates nerve damage and cannot be restored by operation. A hearing aid is preferable to operation in cases in which a high postoperative hearing level cannot reasonably be expected to result. In Day's series of 75 cases, a good result with practical hearing for conversation was obtained in 40, or 54 per cent, of 54 patients operated on between October, 1941, and June, 1944. In 3 cases the fenestra closed but was successfully reopened, making a total of 43, or 80 per cent, with successful results. Average hearing loss for the speech range for pure tones before operation was 48.2 decibels. Following operation, there was an average improvement of 28.5 decibels and an average hearing loss in the speech range of 19.7 decibels.

*Surgeon in Otolaryngology, Children's Hospital, Otolaryngologist and Surgeon, Peter Bent Brigham Hospital, Assistant in Laryngology, Harvard Medical School.

drum were thoroughly cleaned and dried and the canal wall and drum membrane were sprayed with a coating of sulfanilamide. Every four hours 1 gm of sulfathiazole was administered, and if no improvement was noticed, the dose was increased to 1.5 gm every four hours. If sulfathiazole was not tolerated, sulfadiazine was used. This routine, which was continued until the discharge, edema and itching subsided, was successful. The average duration of treatment in this series in a tropical climate was less than seven days.

Radium Therapy for Aerotitis

Irradiation of the nasopharynx by radium for the control of aerotitis proved to be safe and effective prophylaxis and treatment as used by the United States Army Air Forces.¹² The flying personnel treated numbered 6881, but owing to the shifting of personnel only 1129 men were available for observation thirty days or more after the completion of the therapy. The conclusions reached are based on the study of this group. Seventy-four per cent of 636 men with a history of recurrent aerotitis had less difficulty in ventilating their ears during flights. Eighty-nine per cent of the same group showed a marked decrease in the amount of nasopharyngeal lymphoid tissue when examined with a nasopharyngoscope thirty days or more after the third treatment. The beneficial effect of prophylactic irradiation was shown by the drop in incidence of aerotitis in 778 men after high-altitude flights. Following the completion of treatment, the incidence of aerotitis in this group was reduced from twice that in a control group of 922 men with normal nasopharynges to a level almost identical with that in the control group. The principal cause of failure to improve after irradiation treatment was the presence of a large mass of adenoid tissue. For such patients, surgical removal, supplemented by irradiation, would have been more effective. Other contributing factors to failure of treatment were considered to be nasal allergy, chronic sinusitis and psychologic reactions. Treatment consisted in placing two nasopharyngeal applicators, each containing 50 mg of radium sulfate, in the nasopharynx for a period of eight and a half minutes. From one to three treatments were given at intervals of eight days. In 14,045 treatments there was not a single case of burn or ulceration of the nasopharynx or nasal mucous membrane.

Surgery of Facial Nerve

Tickle¹³ reports his observations on 300 operations for peripheral facial paralysis performed since 1930. When interruption of the continuity of the nerve was due to trauma, fresh nerve grafts from the anterior femoral cutaneous nerve were used to bridge the gap. Grafts from either motor or sensory nerves may be employed, but the latter are regarded as preferable. Two types of nerve injury respond to

surgery: trauma to the facial nerve and Bell's palsy. Patients with facial paralysis following trauma should be tested daily with the faradic current. So long as any response occurs, operation should be deferred, but if reaction to the faradic current is lost, the nerve should be investigated immediately. In Bell's palsy, 85 to 90 per cent of patients recover, the remainder can be helped by decompression of the nerve if this is done soon after the onset. As in trauma, the same criteria apply for determining the time to operate. Patients who retain response to the faradic current recover, those who lose this response may never, or only partially, recover. If response to galvanic stimulation is lost in either type of case, operation is useless, for this means atrophy or fibrosis of the facial musculature.

NOSE AND SINUSES

Chemotherapy

Kern¹⁴ condemns the use of sulfonamides in the common cold because of the risk of inducing sensitivity to a drug that may later be required in a more serious infection. Furthermore, the doses employed are usually inadequate to prevent pneumonia, and yet this inadequate dosage can be responsible for a drug-fast strain of the pneumococcus. Administration of these drugs renders the pneumococcus untypable and thereby prevents the use of specific serum therapy in patients with drug-fast pneumococci. Routine administration of the sulfonamides, which may interfere with the development and maintenance of a desirable active immunity to a number of frequent pathogenic organisms, may increase the incidence of pyogenic complications in the respiratory tract in the period immediately following the cold.

Hayden and Bigger¹⁵ gave sulfanilamide lozenges, each containing 0.065 gm of the drug, to a group of troops in an Army training center. A similar group were given lozenges of the same base but lacking the sulfanilamide. The lozenges were administered five times daily for sixteen days. From the observations on these groups, it was concluded that if the sulfanilamide lozenges afforded any protection against colds, it was of such an insignificant degree as to be not worth the trouble, expense and risk involved.

In the treatment of acute sinusitis and its complications, Hauser and Work¹⁶ favor the intramuscular injection of 20,000 units of penicillin every three hours until the optimum result has been obtained. In the treatment of orbital cellulitis, this therapy has replaced every other method of treatment. In the presence of allergic rhinitis with superimposed infection, penicillin therapy eliminates all evidence of suppuration but produces no change in the underlying allergy. The results obtained in chronic sinusitis depend to a large extent on the duration of the disease. When the duration is relatively short, a cure can be accomplished by the in-

might be expected during the normal progress of the disease. Hearing was decreased beyond normal expectancy in 30 cases without audiograms and in 5 with audiograms. In 4 cases deafness first occurred during pregnancy. For progressive deafness to be considered an indication for therapeutic abortion, a definite diagnosis of otosclerosis must first be made. The hearing should be followed carefully before, during and following pregnancy and lactation for evaluation concerning succeeding pregnancies. Otosclerosis should not be considered as an indication for therapeutic abortion in primiparas. A familial history of deafness need not be present and yet may be one of the deciding factors in the decision to interrupt a pregnancy. A multipara may have considerable right to question the continuation of her pregnancy, if accurate otologic evidence obtained at previous pregnancies has shown a marked, sustained loss of hearing. Before therapeutic abortion is decided on, the patient should be informed that otosclerosis is a progressive disease, even without pregnancy, and that hearing aids and lip reading offer considerable help.

Barton⁷ made a study of the effect of pregnancy on the hearing of 133 women who were known to have otosclerosis and who had one or more pregnancies. In 73 patients the hearing was made worse by pregnancy, and in 51 of these the hearing loss occurred during the first pregnancy and persisted in all but 2 of the patients. In multiparas who experienced loss of hearing with the first pregnancy, about 50 per cent showed no further loss with subsequent pregnancies. It was concluded that therapeutic abortion or sterilization is not indicated in women with otosclerosis, since the hereditary nature of the disease has not been conclusively proved and the unfavorable effect of pregnancy on the hearing is not constant.

Penicillin in Otolaryngology

Johnson and his associates⁸ report a series of 23 cases in which a simple mastoidectomy was performed for suppurative mastoiditis following scarlet fever or measles. The mastoid wound was sutured, penicillin being applied to the cavity through a urethral catheter. The recommended dose of the drug was 10,000 units every eight hours for four days. Seventeen patients showed a complete cure after one course of treatment, whereas 6 remained well after a second course. When penicillin was given in adequate dosage, healing of the postaural wound and a dry external auditory canal usually occurred on the fifth postoperative day. If aural discharge recurred, the catheter was reinserted and more penicillin was injected until the ear had completely cleared. Local treatment with penicillin seems preferable to the use of sulfonamides when susceptible organisms are present, because of the absence of any harmful toxic effects, the slight risk of sensitization and the increased speed of healing.

Allman⁹ used penicillin intramuscularly in 511 cases of otitis media caused by scarlet fever. Twenty-seven cases of scarlet-fever mastoiditis were cured in this manner without surgery. In 33 cases of mastoiditis due to scarlet fever, penicillin was used both intramuscularly and locally, these cases required surgical exenteration of the mastoid. Meningitis occurred in 2 patients. In the postoperative treatment of 14 cases of non-scarlet-fever mastoiditis, penicillin was administered by the same method. Ten of these patients had acute and 4 had chronic mastoiditis. Administration of the drug by the intramuscular route was accomplished by giving 20,000 units at the onset and following this by 10,000 units every three hours thereafter day and night until the tympanic membrane and the postaural incision were healed. For local application within the mastoid cavity, 10 cc of a solution containing 500 units of penicillin per cubic centimeter was instilled into the mastoid cavity every four hours when the cavity was large, and 5 cc when it was small. Sodium penicillin was used. The postaural incisions healed by primary intention. Administration of penicillin from the onset of scarlet fever reduces the incidence of ear complications. In a study of 300 patients with scarlet fever in the wards in which no penicillin was administered, acute otitis media developed in 10.9 per cent, whereas in wards in which penicillin was administered, the incidence in 300 cases of scarlet fever was only 5.6 per cent.

Otitis Externa

Senturia's¹⁰ studies on external otitis at Randolph Field, Texas, show that fungi play little part in the inception or persistence of external otitis. Gram-negative bacilli, especially those of the *Pseudomonas* group, were found in a high percentage of cases showing acute desquamative and chronic suppurative external otitis, but no single organism or combination of bacteria occurred frequently enough to be considered a specific cause of external otitis. Bacterial infection produces almost any type of discharge, from a thin serous type to a thick, grayish, purulent secretion. The so-called "blotting-paper" discharge is not pathognomonic of fungus infection. It was concluded that, since no single available chemotherapeutic agent is an effective bactericide and fungicide for use in acute infections of the ear canal, careful examination and observation of all types of external otitis are necessary.

In a series of 90 cases of otitis externa in a tropical climate studied by Simon,¹¹ only 20 per cent showed cultures yielding a fungus. The presence of an organism in culture from otitis externa does not absolutely imply that the organism is the primary agent, it may or may not be the one producing the lesion. In each of the 90 cases, a bacterial growth on culture was obtained, and it was concluded that bacteria are the primary invaders in this disease. In the last 60 cases the external auditory canal and

hemorrhagic inflammation of the soft palate was observed

Nevert²² reports that, with rare exceptions, observations to date suggest that one of the most important factors in late post-tonsillectomy hemorrhage is the reduction of the prothrombin of the blood brought about by the use of acetylsalicylic acid or salicylates. This reduction in prothrombin interferes with coagulation. With the simultaneous administration of Synkavite, a compound similar to vitamin K, the prothrombin-lowering effect of acetylsalicylic acid is overcome and normal coagulation can take place. Rectal suppositories and tablets composed of 0.3 gm of acetylsalicylic acid and 5 mg of Synkavite were used. Suppositories were given to 173 patients, and the tablets to 110 patients. The results were reported as most gratifying, late tonsillar bleeding occurring in only 4 patients among the total of 283 — an incidence of 1.4 per cent. When compared with an incidence of late tonsillar hemorrhage of almost 10 per cent accompanying the former routine, which called for the free use of salicylates alone, the present results demonstrate that proper postoperative care should include measures designed to prevent lowering of the prothrombin content of the blood. It is concluded that salicylates should either be avoided or, if given, combined with a drug such as Synkavite, which prevents hypoprothrombinemia.

Sulfathiazole in Chewing Gum

In treating a series of patients who had infections of the mouth, tonsils or pharynx, Fox and his associates²³ used a tablet of gum containing 0.25 gm of sulfathiazole. One tablet was administered every three hours, except when a severe infection of the throat was present, when the patient was instructed to chew the tablet for an hour and to rest for an hour. In 32 cases of acute lymphoid pharyngitis and follicular tonsillitis, 72 per cent showed a decided decrease in total bacterial counts of cultures made from mouth washings within forty-eight hours, along with complete disappearance of the beta-hemolytic streptococcus from the cultures. In 38 cases of ulcerative stomatitis, a decrease in the total bacterial count was noted in 67 per cent, with a 75 per cent decrease in the beta-hemolytic streptococcus within forty-eight hours. Even more spectacular was the rapid clinical resolution of these conditions. The same results were obtained in the Plaut-Vincent ulcerative type of stomatitis. In chronic mouth conditions, such as salivary adenitis and catarrhal stomatitis, associated with mouth breathing in persons with hyperplastic pansinusitis, a decrease in the total bacterial count was also noticed. Clinical improvement, as demonstrated by the disappearance of mouth odor and coated tongue, was observed. It was concluded in this preliminary report that, from the standpoint of minimal systemic toxicity and maximum local

antibacterial potency, sulfathiazole in chewing gum is the preferable local chemotherapy for infections of oral and pharyngeal mucosa that are susceptible to the sulfonamides. The best clinical results were obtained in conditions of the mouth and pharynx in which the beta-hemolytic streptococcus was the predominant organism.

LARYNX

Hoarseness

Zinn²⁴ points out that hoarseness may result from inflammatory infections of the larynx, trauma, tumors and disturbances of the central and peripheral nervous systems. The diagnosis of functional hoarseness should not be made until all organic lesions have been excluded. This condition requires as careful study and treatment as if a definite lesion were present. It is now generally conceded that 80 per cent of all cases of carcinoma of the larynx are curable by operation if the diagnosis is made while the disease is still intrinsic. In a previously reported series of 25 cases of total laryngectomy, 80 per cent of the patients gave a history of preoperative hoarseness for periods varying from six months to over two years. In another series of 178 cases, hoarseness was a constant symptom, but 100 of the patients, who were not referred until all classic symptoms of carcinoma were present, had to be classed as inoperable. Of 144 cases of carcinoma of the larynx recently examined, 134 patients (93 per cent) gave a history of hoarseness as the first symptom. Jackson and Jackson²⁵ report statistics on 410 cases, in which hoarseness was an early symptom in 95 per cent. Negus²⁶ urges that no patient be continuously hoarse for more than three weeks without laryngeal examination and diagnosis.

Cancer of the Larynx

According to Tucker,²⁷ in a large number of cases surgical cure of cancer of the larynx by laryngofissure and total laryngectomy has been reported, and it is his belief that surgery is the method of choice in the treatment of this condition when adequate excision can be performed. Surgical excision by laryngofissure should give a permanent cure in from 80 to 85 per cent of cases in early intrinsic cancer. In more extensive lesions in areas of the larynx where metastatic extension is more rapid, total laryngectomy is required, and a cure of from 50 to 60 per cent of advanced cases of this type may be expected. When the lesion has extended beyond the cartilaginous framework of the larynx, wide excision of the involved area with removal of the larynx, followed by postoperative irradiation, offers a fair prognosis — possibly 30 to 50 per cent of the patients are cured. The possibility of late recurrence of cancer in the regional lymph nodes, without local recurrence in the larynx, following laryngofissure or local recurrence in the pharynx or trachea following laryngectomy must be kept in

tramuscular injection of penicillin alone. In chronic suppurative disease of the sinuses of long duration, penicillin alone is of little value, but when used in conjunction with adequate sinus surgery, rapid and complete cures were accomplished.

Sinus Disease in Children

According to Taquino,¹⁷ two facts are generally overlooked in sinus disease in children: that it is frequent and that it is often of allergic origin. Diagnosis presents some difficulty because of the age of the patient and the size of the nasal passages. Transillumination of the sinuses is regarded as unreliable, and even radiologic information may be misleading. The same diagnostic procedures that are employed in adults should, however, be carried out in children for the diagnosis of sinus disease. In general, treatment should be of a conservative nature. Removal of the tonsils and adenoids should not be done unless definitely indicated. The routine use of chemotherapy is undesirable. The type of organism found in the sinuses should indicate the chemotherapeutic agent to be employed. Whenever drainage of the sinuses is necessary, it should be carried out by the simplest method. Sinus disease of allergic origin must be treated primarily as an allergy. In both types of sinus disease, attention to the general health is of the greatest importance.

Frontal-Sinus Surgery

In a series of 123 cases in which the Lynch operation for chronic infection of the frontal and ethmoidal sinuses had been performed, Goodale¹⁸ reports that reoperation was necessary in approximately 30 per cent. At the second operation, the causes for failure were noted as follows: obstruction of the nasal frontal passage by adhesions, remnants of the frontal-sinus floor that had given rise to undrained infected pockets in the frontal sinus, and incomplete ethmoidectomy, especially failure to remove orbital extensions of the ethmoid. To maintain the patency of the opening between the frontal sinus and the nasal cavity, a strip of tantalum foil, 1.5 cm. wide and 4.0 cm. long, was sutured by means of fine tantalum wire to the orbital periosteum, at about the position of the pulley. During the previous two years, this technic had been used with excellent results in a total of 8 patients.

PHARYNX AND TONSILS

Monilial Pharyngitis

Tumulty and Michael¹⁹ report a series of 18 patients with monilia infection of the oropharynx. Although the disease usually occurs in undernourished infants or debilitated adults, the patients reported were well nourished young men in good general health. There is no clinical feature of monilial pharyngitis that helps to differentiate it from streptococcal pharyngitis or from pharyngeal diphtheria. Secondary syphilis and Vincent's angina

may also cause some confusion. The diagnosis is made by direct examination of mucosal scrapings and by culture material obtained from diseased sites. Throat swabs should be planted on slants of Loeffler's medium. If monilia are present, small creamy colonies appear after twelve to eighteen hours of incubation. Overnight growths are stained with Loeffler's methylene blue, and either monilia or diphtheria organisms can be demonstrated by this method. In 5 of the cases reported, monilia was considered solely responsible for the acute pharyngitis. In 3 other cases, its significance could not be determined owing to the presence of beta-hemolytic streptococci. In the remaining cases, it was believed to have had no etiologic role.

Poliomyelitis and Recent Tonsillectomy

Anderson²⁰ reports that a severe epidemic of poliomyelitis occurred in Utah in 1943. Of the hospitalized patients, 31.6 per cent had the bulbar or bulbospinal type. A state-wide survey showed the number of tonsillectomies performed to be 1411 in July, 2111 in August and 677 in September. Seventeen of these children developed poliomyelitis within thirty days after operation; all the patients had either the bulbar or bulbospinal type of poliomyelitis. During the same three-month period, 261 cases of poliomyelitis were reported in the state, in which 232 patients were children between the ages of three and sixteen. The incidence of poliomyelitis in the tonsillectomized group was 0.40 per cent, or about two and a half times greater than the 0.15 per cent incidence of poliomyelitis in the child population of the same age group. The total number of bulbar or bulbospinal cases of poliomyelitis in children three to sixteen years of age was 39, and 17 (46 per cent) of these cases had been preceded by a recent tonsillectomy. A comparison of the incidence of bulbar cases in the general child population with the incidence in the tonsillectomized group showed that, during this epidemic, the possibility of contracting bulbar poliomyelitis was sixteen times greater in children immediately after tonsillectomy than in children in the general population.

Post-Tonsillectomy Hemorrhage

According to Singer,²¹ post-tonsillectomy hemorrhage occurs in 5 to 10 per cent of all tonsillectomized patients. In the clinics and hospitals of Central Europe, the incidence of this complication is practically nil because of the practice of giving aminopyrine instead of acetylsalicylic acid. A comparison of the preoperative and postoperative regimes used in this country and abroad show this to be the only significant difference. In 75 patients observed during 1943 who, after tonsillectomy, were placed on an acetylsalicylic acid-free post-tonsillectomy routine, no secondary hemorrhage occurred and, what is regarded as more significant, no case of

CASE 32451

PRESENTATION OF CASE

First admission. A seventy-four-year-old man entered the hospital because of gross urinary bleeding of two weeks' duration. The bleeding was painless and there were no other symptoms. On examination, the left lobe of the prostate was slightly enlarged and firm, the left testicle was atrophied, and there was a reducible left inguinal hernia. Cystoscopy revealed a small, sessile growth with superficial papillary projections located deep in the left ureteral orifice. Treatment consisted in cutting away the tumor in pieces and implanting four radon seeds of 1 millicurie each. The pathological report was carcinoma (Grade III). The patient was discharged on the eleventh day.

Final admission (four years and six months later). During the period following operation, the patient visited the Out Patient Department every six months. The bladder wound healed, leaving a white scar. No recurrence was apparent at any time. The lateral lobes of the prostate became slightly enlarged and more indurated. There was slight inflammatory edema of the bladder outlet. Two years before admission the patient began to be constipated. Approximately six months before admission he began to notice bright-red blood in the stools, continuing until admission, the stools were never black. About a month later he noticed a small painless lump in the right neck that had progressed to 3 cm. in diameter by the time of entry. The patient believed that he had begun to lose ground about a month before admission. His

appetite failed, and he lost all sensation of taste. He had lost 15 pounds in weight during the preceding year. The throat became dry and somewhat sore. A diffuse, dull, crampy epigastric pain unrelated to food and slightly relieved by soda annoyed him constantly. Blood was said to have appeared in the urine at about the same time. Three weeks before admission the skin turned yellow, and the jaundice subsequently deepened. The stools became light colored in the weeks before entry.

On physical examination the patient was thin and jaundiced and spoke with a hoarse voice. On the right side of the neck beneath the sternomastoid muscle was a mass, 3 by 4 cm. in diameter, that was hard and only slightly movable. The chest was clear. The liver extended 4 cm. below the ribs. There was a right indirect hernia, and the right testicle was atrophic. The right lateral lobe of the prostate was firm, with a poorly defined border.

The temperature was 98°F, the pulse 65, and the respirations 15. The blood pressure was 120 systolic, 60 diastolic.

Examination of the blood showed a hemoglobin of 12 gm. per 100 cc. and a white-cell count of 6050. The urine was bile stained, gave a ++ test for albumin and contained rare white cells per high-power field but no red cells. The stools were fluid, brown and grossly bloody. X-ray films failed to reveal metastases in the chest. No definite esophageal lesion was seen, but there was delay in the passage of barium through the lowermost portion of the esophagus where it crossed the aorta. The duodenal bulb was deformed in a manner characteristic of an old ulcer. The only abnormal blood values were a bilirubin of 17 mg. per 100 cc. direct and 20 mg. indirect, a prothrombin time of twice normal and a chloride of 97 milliequiv. per liter. The cephalin-flocculation test was + in twenty-four hours and ++ in forty-eight hours. The acid phosphatase level was 1 unit, and the alkaline phosphatase 163 Bodansky units per 100 cc.

On the day after admission generalized itching of the skin developed. In the next two weeks three diagnostic procedures were performed. Proctoscopy disclosed an obstructing tumor in the rectosigmoid, 14 cm. from the anus, biopsies from

mind, for metastatic lymph nodes have appeared from five to ten years after surgical excision of the primary lesion. The mass should be removed immediately by surgery, radon seeds implanted in the region from which the node was removed and x-ray irradiation applied to the neck. Jackson and Norris²⁸ use the following indications for surgical treatment of cancer of the larynx: lesions occupying the middle third of one cord are suitable for laryngofissure, lesions reaching the anterior commissure and even involving the opposite cord are also amenable to extirpation by the laryngofissure route, but in such cases the so-called "anterior-commissure" technic should be used, lesions in which the growth is cordal but has reached the posterior end of the cord and produced impairment of motility or has extended subglottically ordinarily call for total laryngectomy, as do lesions involving the ventricle or ventricular band, and lesions in which the tumor has invaded cartilage (but not muscle) also call for laryngectomy, provided there are no metastases—where there are metastases, combined laryngectomy and neck dissection should be done. Irradiation is regarded as preferable in lesions unsuitable for laryngofissure in which laryngectomy is contraindicated by the age, physical condition or temperament of the patient, and also for growths inoperable because of extrinsic origin or extension or because of cervical metastases. An analysis of the end results in a series of 150 patients with cancer of the larynx treated at the Temple University Hospital by surgery and irradiation from 1930 to 1937 inclusive showed a combined five-year cure rate of 64 per cent. Of 101 patients with intrinsic lesions who received surgical treatment by either laryngofissure or laryngectomy 80 patients, or about 75 per cent, obtained at least a five-year cure. Nine patients with extrinsic lesions, on whom laryngectomy was performed, died. During the same period, 34 patients were treated by irradiation (protracted fractional technic), 22 with intrinsic and 12 with extrinsic growths, in the former group, a 59 per cent and in the latter a 25 per cent five-year cure rate was obtained.

Hemangioma of the Larynx

Kasabach and Donlan²⁹ state that the possibility of hemangioma should be considered in infants when there is a history of recurring, obstructive dyspnea. The symptoms of hemangioma of the larynx in infants, in order of frequency, are obstructive dyspnea, inspiratory stridor, a hoarse cry, croupy cough, blood-tinged mucus, gross hemorrhage and fever, if there are pulmonary complications. Laryngoscopic examination shows a red or bluish subglottic mass. The presence of other hemangiomas on the body also helps to confirm the diagnosis. Hemangiomas of the larynx in infants are always subglottic, whereas in adults they are usually found on or above the vocal cords. In the treatment of

hemangioma of the larynx in infants, the dyspnea must first be relieved by low tracheotomy, radiation therapy is then begun, using either radium or x-ray. Two cases were reported in which x-ray therapy was used with good results, both children were normally developed and had adequate airways two years or more after the completion of treatment.

Recurrent-Nerve Paralysis

Laszlo and Fiertz³⁰ have been successful in determining the prognosis in cases of recurrent-nerve paralysis following thyroidectomy. The principle of examination follows the same underlying criteria as the electrodiagnosis of any other peripheral-nerve injury. The necessary equipment consists of an electrical apparatus that provides both a straight galvanic and a faradic current. A flat electrode is placed on the sternum and the nerve-testing electrode is put on the motor point for the vocal cord—that is, on the respective side of the Adam's apple. If a faradic response is obtained, the damage is minor and recovery can be expected in about two months. If, in the absence of any faradic response, the cathodal closing contraction is better than the anodal response, the second stage of the reaction of degeneration is present and recovery cannot be expected within less than nine months. If the formula is reversed, a complete reaction of degeneration is present and the outlook is accordingly worse. Whether or not the nerve has been anatomically severed cannot be determined by one examination alone, but if, after two months of biologically correct treatment, re-examination gives the same or a worse formula, the conclusion is that the nerve is cut and further conservative therapy is useless. If, however, the formula or the quality of the contraction has improved, treatment can be continued, although the time for recovery may require one and a half or two years. If no reaction whatever is obtained, the diagnosis is obvious and no benefit may be expected from electrotherapy.

CASE 32451

PRESENTATION OF CASE

First admission. A seventy-four-year-old man entered the hospital because of gross urinary bleeding of two weeks' duration. The bleeding was painless and there were no other symptoms. On examination, the left lobe of the prostate was slightly enlarged and firm, the left testicle was atrophied, and there was a reducible left inguinal hernia. Cystoscopy revealed a small, sessile growth with superficial papillary projections located deep in the left ureteral orifice. Treatment consisted in cutting away the tumor in pieces and implanting four radon seeds of 1 millicurie each. The pathological report was carcinoma (Grade III). The patient was discharged on the eleventh day.

Final admission (four years and six months later). During the period following operation, the patient visited the Out Patient Department every six months. The bladder wound healed, leaving a white scar. No recurrence was apparent at any time. The lateral lobes of the prostate became slightly enlarged and more indurated. There was slight inflammatory edema of the bladder outlet. Two years before admission the patient began to be constipated. Approximately six months before admission he began to notice bright-red blood in the stools, continuing until admission, the stools were never black. About a month later he noticed a small painless lump in the right neck that had progressed to 3 cm. in diameter by the time of entry. The patient believed that he had begun to lose ground about a month before admission. His

appetite failed, and he lost all sensation of taste. He had lost 15 pounds in weight during the preceding year. The throat became dry and somewhat sore. A diffuse, dull, crampy epigastric pain unrelated to food and slightly relieved by soda annoyed him constantly. Blood was said to have appeared in the urine at about the same time. Three weeks before admission the skin turned yellow, and the jaundice subsequently deepened. The stools became light colored in the weeks before entry.

On physical examination the patient was thin and jaundiced and spoke with a hoarse voice. On the right side of the neck, beneath the sternomastoid muscle, was a mass, 3 by 4 cm. in diameter, that was hard and only slightly movable. The chest was clear. The liver extended 4 cm. below the ribs. There was a right indirect hernia, and the right testicle was atrophic. The right lateral lobe of the prostate was firm, with a poorly defined border.

The temperature was 98°F, the pulse 65, and the respirations 15. The blood pressure was 120 systolic, 60 diastolic.

Examination of the blood showed a hemoglobin of 12 gm. per 100 cc. and a white-cell count of 6050. The urine was bile stained, gave a ++ test for albumin and contained rare white cells per high-power field but no red cells. The stools were fluid, brown and grossly bloody. X-ray films failed to reveal metastases in the chest. No definite esophageal lesion was seen, but there was delay in the passage of barium through the lowermost portion of the esophagus where it crossed the aorta. The duodenal bulb was deformed in a manner characteristic of an old ulcer. The only abnormal blood values were a bilirubin of 17 mg. per 100 cc. direct and 20 mg. indirect, a prothrombin time of twice normal and a chloride of 97 milliequiv. per liter. The cephalin-flocculation test was + in twenty-four hours and ++ in forty-eight hours. The acid phosphatase level was 1 unit, and the alkaline phosphatase 163 Bodansky units per 100 cc.

On the day after admission generalized itching of the skin developed. In the next two weeks three diagnostic procedures were performed. Proctoscopy disclosed an obstructing tumor in the rectosigmoid, 14 cm. from the anus, biopsies from

which showed adenocarcinoma (Grade II) Aspiration biopsy of the mass in the neck was reported as showing "metastatic carcinoma consistent with bladder origin" Peritoneoscopy revealed a large blue-gray liver No metastases were seen in the liver or peritoneum Omentum adherent around the gall bladder prevented visualization of that region

On the twelfth, thirteenth, fourteenth and fifteenth days the temperature spiked to 102 to 103°F, with a shaking chill at each daily peak Painful effusion of the right knee developed on the fifteenth day A watery diarrhea, with partial incontinence, was the patient's major difficulty The jaundice persisted In the last three days the general condition deteriorated rapidly On the eighteenth day the patient became comatose and died a few hours later

DIFFERENTIAL DIAGNOSIS

DR PAUL ZAMECNIK I am curious about the occupation of this patient in view of the fact that carcinoma of the bladder is one of the few human tumors in which there is a definite occupational etiology In the German dye industry in the early days, when making aniline and other aromatic amines began, it was found that 30 per cent of the cases of carcinoma of the bladder occurred in dye workers

DR TRACY B MALLORY I can find no record of this man's occupation

DR ZAMECNIK I should also like to know whether any x-ray films of the spine and pelvis were taken

DR MALLORY We have x-ray films, but the radiologist says that they are entirely negative and not worth showing

DR ZAMECNIK The primary assumption may be made in this case that the patient died as a result of metastatic carcinoma, and the problem is then reduced to deciding which of several possibilities may be the primary site One may list what seem to be the likelier possibilities—carcinoma of the bladder, the rectosigmoid and the prostate—and discuss them in reverse order

Three symptoms point to disease in the neck hoarseness, dryness of the throat and loss of taste Carcinoma of the larynx accounts for between 1 and 5 per cent of all carcinomas It can explain the hoarseness and all symptoms in the cervical region, but carcinoma of the larynx usually remains localized until late and seldom metastasizes to a great distance It does not appear to be a good possibility when most of the pathologic findings relate to the abdomen

When one is dealing with metastatic carcinoma of the prostate, the acid phosphatase activity is generally elevated and is practically always elevated when there is metastasis to bone This diagnosis has in its favor the fact that carcinoma of the bladder frequently results from extension

of the process from the prostate, indeed, possibly 50 per cent of carcinomas of the bladder are tensions from the prostate Carcinoma of prostate, however, metastasizes to the bone about 70 per cent of the cases Of this 70 per cent, about 85 per cent are osteoblastic and should be associated with a high acid phosphatase level Therefore, although carcinoma of the prostate is a disease that frequently extends through to the bladder, one would not expect such extracapsular prostatic disease to remain dormant On the whole, one may rule out carcinoma of prostate

We should also consider carcinoma of the rectosigmoid Thirty per cent of carcinomas of the gastrointestinal tract are rectal, and of these, two thirds are rectosigmoid I think that it is unlikely that a metastatic carcinoma would localize in the rectosigmoid region and produce an obstruction It is more probable that disease occurred primarily in this region Carcinomas of the rectosigmoid metastasize freely, usually to the inferior mesenteric nodes and frequently, by extension or metastasis, to the liver, lungs and brain I believe that carcinoma of the rectosigmoid cannot be ruled out

The final possibility is carcinoma of the bladder When all cases of carcinoma of the bladder are taken into account, 75 per cent of the patients fail to survive five years Usually, however, when recurrence occurs it does so locally, and metastases are generally not widespread Death most frequently occurs as a result of obstruction of the ureters or infection of the urine and pyelonephritis The aspiration biopsy of the mass in the neck showed "metastatic carcinoma consistent with bladder origin," so that I assume that it was squamous-cell carcinoma On the other hand, an adenocarcinoma was found in the rectosigmoid and I therefore think that it is sound to assume that there were two separate primary neoplastic processes present in this patient One was carcinoma of the bladder, which was discovered five years previously and which was treated with radon implants There may have been some residual tumor in the submucosa, later metastasizing to the cervical region and possibly extending through into the prostate The latter situation is a rather frequent process My second diagnosis is adenocarcinoma of the rectosigmoid, with metastases to the retroperitoneal nodes, the liver and possibly the mediastinum The terminal event may have been due to cholangitis associated with a partially obstructive jaundice, and the effusion in the knee may have been a result of terminal septicemia

DR EDWARD BENEDICT I did the peritoneoscopy on this patient, and I thought that the findings were consistent with biliary cirrhosis I could not see metastatic carcinoma in either the liver or the peritoneum But, of course, peritoneoscopy is

limited, it shows only surface lesions, and a retroperitoneal carcinoma can easily be missed

CLINICAL DIAGNOSES

Carcinoma of bladder
Carcinoma of rectum

DR. ZAMECNIK'S DIAGNOSES

Carcinoma of urinary bladder, with cervical metastasis and probable extension through to prostate
Adenocarcinoma of rectosigmoid, with metastases to retroperitoneal lymph nodes, liver and possibly mediastinum
Terminal cholangitis and septicemia

ANATOMICAL DIAGNOSES

Colloid carcinoma of gall bladder, with widespread metastases.
Epidermoid carcinoma of bladder, with cervical metastases
Adenocarcinoma of rectum
Adenocarcinoma of prostate
Biliary cirrhosis of liver, slight

PATHOLOGICAL DISCUSSION

DR. MALLORY Dr Zamecnik listed three possibilities carcinoma of the bladder, infiltrating adenocarcinoma of the rectum and a probable cancer of the prostate. The patient had all three. The bladder at the time of autopsy showed no evidence of recurrence, but a large lymph node in the neck from which the aspiration biopsy had been taken, when removed at autopsy, showed a poorly differentiated squamous-cell carcinoma entirely consistent with bladder origin and closely resembling a bladder tumor. We also verified the fact that he had carcinoma of the prostate, which was a well differentiated adenocarcinoma resembling in no way the tumor of the bladder, and we could be quite certain that it was a second primary tumor. The tumor of the rectum was also an adenocarcinoma, but once more was well differentiated, slightly polypoid in character, showing slight invasion of the wall, and apparently entirely localized. On the other hand, the retroperitoneal lymph nodes were diffusely and markedly enlarged and, on gross examination, obviously filled with carcinoma.

We also found at autopsy a gall bladder that had a thick, firm, hard wall and a diffuse thickening of the wall of the common bile duct. There was a large stone in the gall bladder, as there usually is in cases of primary carcinoma of the gall bladder. The gall-bladder tumor showed quite marked mucin formation, and the majority of the metastatic lymph nodes showed a frank colloid carcinoma, whereas there was no suggestion of colloid formation in the rectal tumor. Our final opinion on this case was that the patient had four inde-

pendent primary cancers and that it was the cancer of the gall bladder that produced the metastases and resulted in death, and not the other three that were apparent on clinical examination

CASE 32452

PRESENTATION OF CASE

A twenty-seven-year-old crane operator entered the hospital for study of a "rib tumor" discovered during a routine x-ray examination.

For several years the patient had experienced moderate pain in the right shoulder posteriorly that occurred particularly when he remained in the sitting position for any length of time. Occasionally he had to stop playing the piano because of this pain, which never seriously interfered with other activities, however. Four months before entry a routine chest x-ray film taken at his place of employment was found to show a "rib tumor." Review of a similar chest plate taken five years previously disclosed a smaller tumor in the same location. Two weeks before entry, the patient had an attack of "pleurisy" with sharp pain that was aggravated on inspiration and was most marked over the sixth costal rib on the right side. This episode lasted two days but did not interfere with any activity. There had been no cough, fever, chills, night sweats, fatigue, dyspnea, dysuria, flank pain or weight loss.

Physical examination was negative except for markedly impaired hearing in the left ear.

The temperature, pulse and respirations were normal. The blood pressure was 140 systolic, 100 diastolic.

Examination of the blood showed a white-cell count of 10 550 and a hemoglobin of 13.8 gm. The total protein was 7.0 gm, the phosphorus 2.6 mg and the alkaline phosphatase 3.0 Bodansky units per 100 cc. A blood Hinton test was negative.

X-ray examination of the chest revealed localized cystic widening of the posterior medial aspect of the right second rib in the region of the rib angle. X-ray films of the pelvis, arms and hands were normal.

On the tenth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. HUGH F. HARE* We have three sets of x-ray films showing the tumor. The first film reveals a lesion involving the second rib. There is only slight expansion of the rib, the lesion appears cystic and involves the cortex, but there is no evidence of any break through the cortex. Approximately 3 cm. of bone was involved at that time. The second film, which was taken five years

*Radiologist, Lahey Clinic

which showed adenocarcinoma (Grade II) Aspiration biopsy of the mass in the neck was reported as showing "metastatic carcinoma consistent with bladder origin" Peritoneoscopy revealed a large blue-gray liver No metastases were seen in the liver or peritoneum Omentum adherent around the gall bladder prevented visualization of that region

On the twelfth, thirteenth, fourteenth and fifteenth days the temperature spiked to 102 to 103°F, with a shaking chill at each daily peak Painful effusion of the right knee developed on the fifteenth day A watery diarrhea, with partial incontinence, was the patient's major difficulty The jaundice persisted In the last three days the general condition deteriorated rapidly On the eighteenth day the patient became comatose and died a few hours later

The final possibility is carcinoma of the bladder When all cases of carcinoma of the bladder are taken into account, 75 per cent of the patient fail to survive five years Usually, however, when recurrence occurs it does so locally, and metastases are generally not widespread Death most frequently occurs as a result of obstruction of the ureters or infection of the urine and pyelonephritis The aspiration biopsy of the mass in the neck showed "metastatic carcinoma consistent with bladder origin," so that I assume that it was a squamous-cell carcinoma On the other hand, an adenocarcinoma was found in the rectosigmoid and I therefore think that it is sound to assume that there were two separate primary neoplastic processes present in this patient One was carcinoma of the bladder, which was discovered five years previously and which was treated with radon implants There may have been some residuum in the submucosa, later metastasizing to the cervical region and possibly extending through into the prostate The latter situation is a rather frequent process My second diagnosis is adenocarcinoma of the rectosigmoid, with metastases to the retroperitoneal nodes, the liver and possibly the mediastinum The terminal event may have been due to cholangitis associated with a partially obstructive jaundice, and the effusion in the knee may have been a result of terminal septicemia

DR EDWARD BENEDICT I did the peritoneoscopy on this patient, and I thought that the findings were consistent with biliary cirrhosis I could not see metastatic carcinoma in either the liver or the peritoneum But, of course, peritoneoscopy is

limited, it shows only surface lesions, and a retroperitoneal carcinoma can easily be missed

CLINICAL DIAGNOSES

Carcinoma of bladder
Carcinoma of rectum

DR. ZAMECNIK'S DIAGNOSES

Carcinoma of urinary bladder, with cervical metastasis and probable extension through to prostate
Adenocarcinoma of rectosigmoid, with metastases to retroperitoneal lymph nodes, liver and possibly mediastinum
Terminal cholangitis and septicemia

ANATOMICAL DIAGNOSES

Colloid carcinoma of gall bladder, with widespread metastases.
Epidermoid carcinoma of bladder, with cervical metastases
Adenocarcinoma of rectum
Adenocarcinoma of prostate
Biliary cirrhosis of liver, slight

PATHOLOGICAL DISCUSSION

DR. MALLORY Dr Zamecnik listed three possibilities: carcinoma of the bladder, infiltrating adenocarcinoma of the rectum and a probable cancer of the prostate. The patient had all three. The bladder at the time of autopsy showed no evidence of recurrence, but a large lymph node in the neck from which the aspiration biopsy had been taken, when removed at autopsy, showed a poorly differentiated squamous-cell carcinoma entirely consistent with bladder origin and closely resembling a bladder tumor. We also verified the fact that he had carcinoma of the prostate, which was a well differentiated adenocarcinoma resembling in no way the tumor of the bladder, and we could be quite certain that it was a second primary tumor. The tumor of the rectum was also an adenocarcinoma, but once more was well differentiated, slightly polypoid in character, showing slight invasion of the wall, and apparently entirely localized. On the other hand, the retroperitoneal lymph nodes were diffusely and markedly enlarged and, on gross examination, obviously filled with carcinoma.

We also found at autopsy a gall bladder that had a thick, firm, hard wall and a diffuse thickening of the wall of the common bile duct. There was a large stone in the gall bladder, as there usually is in cases of primary carcinoma of the gall bladder. The gall-bladder tumor showed quite marked mucin formation, and the majority of the metastatic lymph nodes showed a frank colloid carcinoma, whereas there was no suggestion of colloid formation in the rectal tumor. Our final opinion on this case was that the patient had four inde-

pendent primary cancers and that it was the cancer of the gall bladder that produced the metastases and resulted in death, and not the other three that were apparent on clinical examination

CASE 32452

PRESENTATION OF CASE

A twenty-seven-year-old crane operator entered the hospital for study of a "rib tumor" discovered during a routine x-ray examination.

For several years the patient had experienced moderate pain in the right shoulder posteriorly that occurred particularly when he remained in the sitting position for any length of time. Occasionally he had to stop playing the piano because of this pain, which never seriously interfered with other activities, however. Four months before entry a routine chest x-ray film taken at his place of employment was found to show a "rib tumor." Review of a similar chest plate taken five years previously disclosed a smaller tumor in the same location. Two weeks before entry, the patient had an attack of "pleurisy" with sharp pain that was aggravated on inspiration and was most marked over the sixth costal rib on the right side. This episode lasted two days but did not interfere with any activity. There had been no cough, fever, chills, night sweats, fatigue, dyspnea, dysuria, flank pain or weight loss.

Physical examination was negative except for markedly impaired hearing in the left ear.

The temperature, pulse and respirations were normal. The blood pressure was 140 systolic, 100 diastolic.

Examination of the blood showed a white-cell count of 10,550 and a hemoglobin of 13.8 gm. The total protein was 7.0 gm, the phosphorus 2.6 mg and the alkaline phosphatase 3.0 Bodansky units per 100 cc. A blood Hinton test was negative.

X-ray examination of the chest revealed localized cystic widening of the posterior medial aspect of the right second rib in the region of the rib angle. X-ray films of the pelvis, arms and hands were normal.

On the tenth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. HUGH F. HARE* We have three sets of x-ray films showing the tumor. The first film reveals a lesion involving the second rib. There is only slight expansion of the rib, the lesion appears cystic and involves the cortex, but there is no evidence of any break through the cortex. Approximately 3 cm of bone was involved at that time. The second film, which was taken five years

*Radiologist, Labey Clinic

later, shows an increase in the size of the tumor, as well as greater expansion of the rib than at the examination five years previously. In a third film taken a month after the second one, the lesion is practically unchanged, appearing multilocular, cystic and expansile.

The first problem that must be considered, if the diagnosis of rib tumor is correct, is whether the lesion was benign or malignant. A tumor that lasted for five years is quite likely to be benign, and we have sufficient evidence in the normal blood findings, the negative Hinton test and the normal blood protein, phosphorus and alkaline phosphatase that this was a localized process. We have further evidence that it was not malignant in that the lungs were clear. One possibility that should never be overlooked in a bone tumor, however, is a reticulum-cell sarcoma, which is a slowly growing lesion and is present a number of years before symptoms become apparent. I do not believe that we need consider plasmocytoma with a duration of five years, but we must consider an enchondroma or chondroma that may have become malignant. Against malignancy, however, is the fact that in this tumor we cannot see any break through the cortex. Therefore, I think that we can rule out a malignant lesion.

Of the benign lesions we must consider bone tumors and granulomas. I do not believe that we can make a differential diagnosis between granulomas and benign tumors from the x-ray films. The most frequent tumor that is found in this location is the giant-cell tumor. Out of a series of 400 cases described by Copeland and Geschickter* 25 per cent were giant-cell tumors of the rib. Another point in favor of bone tumor is that the patient was in the correct age group, being under thirty. Another possibility is bone cyst. The patient was older than the average patient with bone cyst, and the lesion is usually not multilocular, on the other hand, it was close to the epiphyseal margin, cysts generally occurring in such a location or in the metaphysis of the bone.

Proceeding to the granulomas, we should consider fibrous dysplasia, localized eosinophilic granuloma and ossifying fibroma, all of which can fairly well be included because of the fact that this was a multilocular lesion and had been present for a long time. It would not surprise me to find that this lesion belongs in the group of granulomas, because I have seen similar cases. The next possibility is a neurofibroma or von Recklinghausen tumor that had grown into the rib. These are extremely slowly growing processes. There is certain evidence in the x-ray films that could be so interpreted. The long-standing history, however, and the fact that the lesion was multilocular make me favor a giant-cell tumor.

DR JAMES R. LINGLEY: What about the possibility of localized osteitis fibrosa cystica? Such a lesion is not too infrequent in the ribs. We have had several cases in the younger age group.

DR HARE: I think that that is a good possibility, but I included it when I mentioned fibrous dysplasia. It is just a difference in terminology.

CLINICAL DIAGNOSIS

Benign rib tumor

DR HARE'S DIAGNOSIS

Benign giant-cell tumor

ANATOMICAL DIAGNOSIS

Fibrous dysplasia of rib.

PATHOLOGICAL DISCUSSION

DR TRACY B. MALLORY: The rib was resected, and a tumorlike expansion was found. On cutting into this it was seen to be filled with solid material, somewhat gritty in character. Microscopic examination showed marked thinning of the cortex. The marrow cavity was filled with connective tissue in which were many trabeculae of rather poorly formed bone—in other words, the characteristic picture of fibrous dysplasia. There was no cystic cavity that we could find, it was therefore not a true bone cyst.

The question comes up how cases of this type should be handled and how radical one should be in the treatment. Fibrous dysplasia is a chronic lesion that rarely if ever heals completely, but once the patient has passed beyond puberty, the extension is slow and usually stops completely. There is no record of a case of fibrous dysplasia that was followed by osteogenic sarcoma or other form of malignant tumor, so that there is no probability of harm to the patient if it is left untreated. When it occurs in the long bones there is the possibility of pathologic fracture. In the rib that is fairly unlikely, and I think that, if there had been any way in which the diagnosis could have been established, there was not much need for operating on this man. His disability was so slight that he was able to go through three years of military service.

Dr Shipman, this was a patient of yours. Do you wish to add anything?

DR THOMAS L. SHIPMAN: There is little that I can add. The second x-ray film was taken at a time when the patient was being re-employed after discharge from the service. The swelling of the rib five years previously had been missed, but I do not believe that we need apologize for that. We did spot the lesion in the rib in the later film and referred him to the hospital for treatment.

COUNCIL MEETING

A STATED meeting of the Council of the Massachusetts Medical Society was held on October 2, 1946.

On the recommendation of the Committee on Arrangements, the length of the annual meeting in 1947 was extended to cover three instead of the usual two and a half days. In this connection, acting on the recommendation of the Committee on Postwar Planning, the Council directed the Committee on Arrangements to provide for adequate discussion of some topic in medical economics.

Acting also on the recommendation of the Committee on Postwar Planning, the Council authorized the appointment of a special committee to study the medical resources of the Commonwealth, especially regarding how best to mobilize these resources in

time of war or other disaster. This committee will act with a similar committee of the American Medical Association, which will direct its attention to the same subject on the national level.

In connection with the plan to provide medical care for veterans by civilian physicians, the Council agreed to differentiate the specialist and the general practitioner. A communication from the Veterans Bureau indicated that this was necessary if the plan was to go forward. Such a differentiation and the formula by which it will be arrived at were agreed on only for the purposes of the Veterans Administration. The Council likewise agreed that the fee schedule adopted by the Council on April 10, 1946, be reduced by 20 per cent when the services called for in the schedule are rendered by a general practitioner.

Two communications, one from the John Hancock Life Insurance Company and the other from the Liberty Mutual Insurance Company, were referred to the Committee on Public Relations for study by a subcommittee set up for this purpose. These communications dealt with the same subject—the merits of sickness-insurance plans sponsored by old-line insurance companies.

BAL—A CURE FOR HEAVY-METAL POISONING

THE ill wind that blew chlorine gas from the German lines across no man's land in World War I and that started a race for the development of more and deadlier chemicals for use in warfare has now blown in some good. During the present war the search for antidotes to neutralize the action of arsenical vesicants, one of the most potent of which is lewisite, has resulted in the discovery of a therapeutic agent that is effective in counteracting the local and systemic effects of poisoning with arsenicals and with some other heavy metals. The agent is 2,3-mercaptopropanol and has been called BAL (British anti-lewisite). Announcement of the development and properties of this substance has been withheld until recently for reasons of security.

The discovery was made by Peters and his associates at Oxford and was based on earlier American work, which suggested that the toxic action of

arsenic on cells is due to the inactivation of thiol-containing enzymes. A search for other thiol compounds that would compete more effectively for the arsenic resulted in the development of BAL. Many different agencies and groups of workers in Great Britain and in the United States collaborated in these investigations throughout the latter part of the war, and the clinical studies in particular have continued since the close of hostilities. Announcements of the discovery of BAL, together with brief accounts of its pharmacologic and toxicologic properties and of the results of preliminary clinical trials in cases of arsenical and mercurial poisoning, have recently been made.^{1, 2}

Experiments have shown that trivalent arsenicals exert their toxic action by combination with -SH groups of the activating protein of enzyme systems. Tissue respiration is interfered with by the action of the arsenicals on the large group of -SH enzymes essential for carbohydrate transformations and fat metabolism. The enzyme inhibitions produced by lewisite and arsenic can generally be prevented by BAL or by closely related dithiols. Furthermore, even when established, these inhibitions can be reversed by BAL and to a lesser extent by glutathione. In this reversal, BAL exhibits greater affinity for arsenic than do the thiols of the attacked tissue. Certain inhibitions produced by arsine, however, are actually enhanced by BAL, apparently because of the inherent toxicity of BAL itself for the enzyme system attacked by the arsine.

If trypanosomes or spermatozoa are subjected to lethal concentrations of arsenic they lose all motility and show early degenerative changes. If BAL is added, they regain their motility and normal cytologic appearance. The arsenic is actually removed from the damaged cells, as shown by an increase in the arsenic content of the supernatant fluid. BAL was found to be highly effective in the treatment of systemic poisoning in rabbits even when given several hours after the toxic dose of an arsenical.

It was also found that human beings could tolerate effective doses of BAL. Untoward reactions, however, were encountered when larger doses were used. An intramuscular dose of 5 mg per kilogram of BAL in oil may cause a patient some discomfort in

the form of lacrimation, burning of the lips, drying of the mouth and throat, generalized muscular aching, restlessness and nervousness, but no severe reactions were encountered and the effects of smaller doses were minimal. The untoward reactions to BAL seldom persisted for more than thirty minutes, and injections could be repeated at four-hour intervals.

BAL has been used in the treatment of the various arsenical reactions that occur during the course of the treatment of syphilis. These have included arsenical encephalitis, dermatitis, agranulocytosis, fever and jaundice. The early reports indicate a dramatic amelioration of symptoms and a marked reduction in the expected mortality. One interesting feature of BAL therapy in both experimental and clinical arsenic poisoning has been the extremely rapid increase in the excretion of arsenic that follows immediately after the injection of the antidote.

Extensive studies have also been made on the antidotal effects of BAL in experimental mercury poisoning, and the results have been striking. Apparently the interaction of one mol of BAL with one of bivalent mercury in vitro results in the formation of an insoluble compound, but the addition of another mol of BAL produces a substance that is difficult to dissociate but highly soluble. The efficacy of BAL in the treatment of mercurial poisoning is considered to be due to the rapid formation and excretion of the latter.

In the case of both mercurial and arsenical poisoning the efficacy of treatment is greatly decreased the longer it is delayed. Most dogs were protected, however, as long as two or three hours after intravenous injection and five hours after oral administration of mercuric chloride. When treatment was delayed for five hours after ingestion, in most fatal cases death was not associated with renal insufficiency but rather was the result of a severe gastroenteritis, which often was far advanced before the first dose of BAL was administered.

Clinical trials of BAL in human arsenical and mercurial poisoning were reported by Luetscher at the recent meeting of the American Society for Clinical Investigation.³ Dermatitis was the most frequent form of arsenic intoxication and responded

to intunction or injection of BAL. The results in cases of hepatitis and blood dyscrasias were less striking. No deaths occurred in the 30 consecutive cases of arsenical intoxication that were treated with this drug. An increased urinary excretion of arsenic regularly followed the BAL treatment in cases of dermatitis, appearing each time that the course of treatment was repeated. This increase coincided with the appearance of BAL-like material in the urine. In cases of hepatitis, arsenic excretion was not regularly affected by the injections of BAL. Luetscher also reported apparent benefit from large doses of BAL in the treatment of 26 cases of mercurial poisoning. The mortality was about half the previous rate for the Johns Hopkins Hospital. The most striking features of BAL therapy were the prompt relief of even the most alarming symptoms, the rapidity with which the patients made a complete recovery and the low incidence of significant renal complications.

BUREAU OF CLINICAL INFORMATION

All secretaries of various medical groups, such as special societies and alumni associations, are requested to notify the Bureau of Clinical Information regarding scheduled meetings, annual dinners and so forth. If such data are on file, it is hoped that duplication of dates can be avoided.

DEATHS

CONRO—Arthur C. Conro, M.D., of Attleboro, died August 18. He was in his seventy-seventh year.

Dr. Conro received his degree from Chattanooga Medical College in 1901. He was a member of the New England Otological and Laryngological Society. His widow and a son survive.

CROSBY—L. Marshall Crosby, M.D., of Wakefield, died October 24. He was in his seventieth year.

Dr. Crosby received his degree from Dalhousie University Faculty of Medicine, Halifax, Nova Scotia, in 1901. He was a former president of the Middlesex East District Medical Society and a fellow of the American Medical Association. His widow survives.

O'DEA—Patrick J. O'Dea, M.D., of Fitchburg, died September 25. He was in his sixtieth year.

Dr. O'Dea received his degree from University of Vermont College of Medicine in 1912.

SULLIVAN—Arthur J. Sullivan, M.D., of Fall River, died August 6. He was in his fifty-seventh year.

Dr. Sullivan received his degree from Jefferson Medical College of Philadelphia in 1912. A brother and a sister survive.

COMMENT

Diseases reported at an incidence above the seven-year median included anterior poliomyelitis, chicken pox, diphtheria, German measles, measles, meningococcal meningitis, Salmonella infections and whooping cough.

Diseases reported below the median prevalence included bacillary dysentery, mumps, lobar pneumonia, scarlet fever and undulant fever.

Diphtheria continued to rise for the fifth consecutive month, the incidence being over five times the median prevalence. It is the highest for September in thirteen years.

Although above the median prevalence, poliomyelitis had an incidence of less than two thirds that of last year.

Undulant fever is reported at the lowest in seven years.

Lobar pneumonia has reached an all-time low.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from Amherst, 1, Barre, 1, Bellingham, 1, Boston, 9, Chicopee, 1, East Bridgewater, 1, Everett, 2, Falmouth, 1, Gardner, 1, Gloucester, 2, Greenfield, 1, Leverett, 1, Lowell, 2, Lunenburg, 1, Lynn, 2, Malden, 2, Medford, 2, Montague, 1, Natick, 1, Newton, 2, Northampton, 1, North Adams, 7, Northridge, 1, Northfield, 2, Revere, 2, Shelburne, 2, Shrewsbury, 1, Southboro, 1, South Hadley, 1, Springfield, 1, Sudbury, 1, Sutton, 1, Walpole, 3, Waltham, 5, Watertown, 1, Wayland, 1, Webster, 1, Wellesley, 2, Weymouth, 1, Worcester, 29, total, 99.

Diphtheria was reported from Boston, 23, Cambridge, 2, Everett, 1, Hanson, 1, Leominster, 1, Medford, 1, New Bedford, 2, Somerville, 19, Worcester, 1, total, 51.

Dysentery, bacillary, was reported from Boston, 2, Wrentham (State Hospital) 3, total, 5.

Lymphocytic choriomeningitis was reported from Agawam, 1, total, 1.

Malaria was reported from Attleboro, 1, Boston, 4, Brockton, 2, Cambridge, 2, Dedham, 1, Hingham, 1, Lanesboro, 1, Lynn, 1, Newton, 3, Peabody, 1, Quincy, 1, Somerville, 1, Southboro, 1, Springfield, 1, Woburn, 1, Worcester, 1, total, 23.

Meningitis, meningococcal, was reported from Adams, 1, Boston, 1, Chicopee, 1, Fitchburg, 1, Leominster, 1, Lowell, 1, Lynn, 1, Newburyport, 1, total, 8.

Meningitis, Pfeiffer bacillus, was reported from Haverhill, 1, total, 1.

Meningitis, pneumococcal, was reported from Chicopee, 1, Mansfield, 1, total, 2.

Meningitis, streptococcal, was reported from Cambridge, 1, total, 1.

Meningitis, other forms, was reported from Boston, 2, total, 2.

arsenic on cells is due to the inactivation of thiol-containing enzymes. A search for other thiol compounds that would compete more effectively for the arsenic resulted in the development of BAL. Many different agencies and groups of workers in Great Britain and in the United States collaborated in these investigations throughout the latter part of the war, and the clinical studies in particular have continued since the close of hostilities. Announcements of the discovery of BAL, together with brief accounts of its pharmacologic and toxicologic properties and of the results of preliminary clinical trials in cases of arsenical and mercurial poisoning, have recently been made.^{1, 2}

Experiments have shown that trivalent arsenicals exert their toxic action by combination with $-SH$ groups of the activating protein of enzyme systems. Tissue respiration is interfered with by the action of the arsenicals on the large group of $-SH$ enzymes essential for carbohydrate transformations and fat metabolism. The enzyme inhibitions produced by lewisite and arsenic can generally be prevented by BAL or by closely related dithiols. Furthermore, even when established, these inhibitions can be reversed by BAL and to a lesser extent by glutathione. In this reversal, BAL exhibits greater affinity for arsenic than do the thiols of the attacked tissue. Certain inhibitions produced by arsine, however, are actually enhanced by BAL, apparently because of the inherent toxicity of BAL itself for the enzyme system attacked by the arsine.

THE EFFECT OF ANTICOAGULANTS ON THE PENICILLIN THERAPY AND THE PATHOLOGIC LESION OF SUBACUTE BACTERIAL ENDOCARDITIS*

WALTER S. PRIEST, M.D.,† JACQUES M. SMITH, M.D.,‡ AND CHARLES J. MCGEE, M.D.§

CHICAGO

THE nature of the valvular lesions in subacute bacterial endocarditis makes the use of anticoagulants appear a logical procedure in the prevention of fibrin formation. Such agents should thereby keep the vegetative process at a minimum and theoretically render the bacteria more accessible to antibacterial agents. Also, in theory, the frequency of embolism should be reduced.

Following the isolation of heparin and the demonstration of its ability to prolong the coagulation time of blood, many workers used this substance alone or in combination with chemotherapeutic and other agents in the treatment of subacute bacterial endocarditis. The results of these efforts are summed up by McLean et al.,¹ Lichtman,² Katz and Elek,³ and Hines and Kessler.⁴ From his own experience and that of others, Katz concluded that the use of heparin in subacute bacterial endocarditis should be abandoned. Leach and his co-workers⁵ were unable to find at autopsy any significant effect of either heparin or the sulfonamides on the valvular lesions; in addition, the vegetations were swarming with organisms.

Because of the reports of McLean and Leach, the use of anticoagulants was not considered in June, 1943, when our studies on the effect of what were then regarded as large doses of penicillin on subacute bacterial endocarditis were begun. But Loewe,⁶ who at the same time was studying the effect of similar penicillin dosage (200,000 units a day), was also using heparin, administered intramuscularly in Pitkin menstuum, and considered it essential to success. This opinion was maintained in a subsequent paper.⁷ In December, 1943, Dr. Loewe kindly supplied us with sufficient heparin in Pitkin menstuum for a small series of patients. It was our

purpose to treat an equal number of patients with and without anticoagulants, such as heparin and dicumarol,^{||} and also to determine the relative efficacy of the compounds.

EFFECT ON EFFICACY OF PENICILLIN

To date, we have employed penicillin in 37 cases of subacute bacterial endocarditis, in all but 2 of which administration was by continuous intravenous drip. The clinical results in the first 34 cases, which furnished the material analyzed in this report, were reported elsewhere.⁸ Eight patients received heparin alone, 3 received dicumarol alone, 4 received heparin and dicumarol and 19 were treated without anticoagulants.

When heparin and dicumarol were used in the same patient, one drug was used during half the course of penicillin therapy and the other during the remainder, or one was used during a full course and the other during a subsequent course.

In treating the patient in Case 1, it was found that digitals partially or completely nullified the effect of heparin. Hence, in subsequent patients, dicumarol was used whenever digitalization became necessary. The pertinent data concerning the patients receiving anticoagulants are summarized in Table 1.

In Cases 1, 3, 4, 5, 6, 7, 8 and 20, all or part of the heparin was administered subcutaneously or intramuscularly in Pitkin menstuum. Whether given subcutaneously or intramuscularly or even in combination with local anesthetics, this material proved so painful that all but 2 of the patients receiving it refused to continue the treatment. Liquid heparin** was therefore added to the penicillin saline intravenous mixture. Determinations of the coagulation time by the Lee-White modification of Howell's method were made daily and frequently twice daily, except in Case 6, in which the capillary method was used. An attempt was made to maintain the coagulation time between 30 and 60 minutes, as recom-

MISCELLANY

CAMPAIGN TO COMBAT HEART DISEASE

The initiation of a nationwide program of public education and information on diseases of the heart was recently announced by officials of the American Heart Association, Incorporated

The program, according to Dr Howard F West, of Los Angeles, president of the association, will have as its prime purpose "the dissemination of educational information to the public in a broad effort to retard the rapid increase of heart disease throughout the nation"

"Fatalities ascribed to diseases of the heart," Dr West said, "are greater than the total of the next five leading causes of death. It is essential, therefore, that the public know more about the significance of blood pressure, infections, obesity, rheumatic fever and other factors which contribute to various types of heart disease"

It is estimated that there are more than 4,000,000 people in the United States today who have heart disease. Diseases of the heart and blood vessels, including cerebral hemorrhage, accounted for 575,000 deaths in 1944. Fatalities from the five other leading causes in 1944 were as follows: cancer, 171,000, accidental deaths, 95,000, nephritis, 92,000, pneumonia, 64,000, and tuberculosis, 55,000. In addition to accounting for more fatalities than these five causes combined, heart disease is responsible for an annual loss of more than 100,000,000 work days.

Officials of the American Heart Association state that the association's program will call for emphasis on educational work with schools, parent-teacher associations and other groups concerned with children because of the importance of rheumatic fever and heart disease. According to recent surveys, this scourge of children causes more than five times as many deaths as the combined total of deaths from infantile paralysis, scarlet fever, diphtheria, measles, meningitis and whooping cough. It is a serious disease among adults, too, as illustrated by the estimated 40,000 veterans who acquired the disease during their recent military service.

The war forcibly dramatized the need for a national health program designed to retard the increase in heart disease cases. An estimated 10 per cent of the men rejected by Selective Service were disqualified because of cardiovascular diseases. In a survey of a special sampling of 5000 rejectees for cardiovascular diseases in five major cities, — Chicago, New York, Boston, Philadelphia and San Francisco, — 50 per cent had been disqualified because of rheumatic heart disease. The second greatest cause of rejection due to cardiovascular diseases was hypertension, which accounted for nearly 26 per cent of the disqualifications.

The educational campaign of the American Heart Association will reach its climax during National Heart Week, to begin on February 9, 1947, which includes St Valentine's Day. It is expected that all branches of medicine, pharmacy, insurance, industry and many other groups interested in health and public welfare will co-operate fully.

Supporting groups will include the following national organizations, which comprise the American Council on Rheumatic Fever of the American Heart Association, American Academy of Pediatrics, American Association of Medical Social Workers, American College of Physicians, American Hospital Association, American Medical Association, American Nurses Association, American Public Health Association, American Rheumatism Association, American School Health Association, National Organization for Public Health Nursing

and National Society for Crippled Children and Adults. The collaboration of the United States Public Health Service, National Tuberculosis Association and others is expected.

NOTICES

ANNOUNCEMENTS

Dr Joseph Factor announces the removal of his office to 475 Commonwealth Avenue, Boston

Dr James S Mansfield, having returned from military service, is resuming the practice of internal medicine at 12 Bay State Road, Boston

BOSTON GASTROENTEROLOGICAL SOCIETY

The next meeting of the Boston Gastroenterological Society will be held in the New Cheever Amphitheater, Dowling Building, Boston City Hospital, on Wednesday, November 13, at 12 noon. Dr Frank H Lahey will speak on the subject "The Management of Biliary-Tract Disease."

NEW ENGLAND ROENTGEN RAY SOCIETY

The next meeting of the New England Roentgen Ray Society will be held at the Hotel Beaconsfield on Friday, November 15. The x-ray conference at 4:30 p.m. will be devoted to therapy of benign lesions. At 8:00 p.m., Dr Maurice Lenz will speak on the subject "Cancer of the Breast."

SOUTH END MEDICAL CLUB

The next regular meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, November 19, at twelve noon. Dr Norman H Boyer will speak on the subject "Some Clinical Aspects of Coronary Artery Disease." Dr Samuel Grossman will preside.

Physicians are cordially invited to attend.

AMERICAN MEDICAL ASSOCIATION

At the Centennial Session of the American Medical Association, to be held in Atlantic City, June 9 to 13, 1947, the Scientific Exhibit will include both the history of medicine during the past century and the latest developments of medical science.

Application blanks for space are now available. All applicants must fill out the regular form. Applications close on January 13, 1947, after which time the Committee on Scientific Exhibit will make its decision and notify the applicants.

Application blanks for space should be procured as soon as possible. They are available from the Director, Scientific Exhibit, American Medical Association, 535 North Dearborn Street, Chicago 10, Illinois.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, NOVEMBER 14

FRIDAY, NOVEMBER 15			
*9:00-10:00 a.m.	Carcinoma in situ	Dr Tracy B Mallory	Joseph H Pratt Diagnostic Hospital
*10:00 a.m.-12:00 m.	Medical Staff Rounds	Peter Bent Brigham Hospital	
MONDAY, NOVEMBER 18			
*12:15-1:15 p.m.	Clinicopathological Conference	Peter Bent Brigham Hospital	
TUESDAY, NOVEMBER 19			
*12:15-1:15 p.m.	Clinicoroentgenological Conference	Peter Bent Brigham Hospital	
WEDNESDAY, NOVEMBER 20			
*9:00-10:00 a.m.	Certain Peculiarities of Brain Metabolism	Dr David Rapport	Joseph H Pratt Diagnostic Hospital
*10:30-11:30 a.m.	Medical Clinic	Isolation Building Amphitheater, Children's Hospital	
*12:00 m.	Clinicopathological Conference (Children's Hospital)	Amphitheater, Peter Bent Brigham Hospital	
*2:00-3:00 p.m.	Combined Clinic by the Medical, Surgical and Orthopedic Services	Amphitheater, Children's Hospital	

*Open to the medical profession

(Notices continued on page xiv)

mended by Loewe, and it was found somewhat easier to hold it to these limits when liquid heparin was added to the penicillin solution

By either method of administration there was considerable individual variation in response. In Case 1 the administration of 300 and 200 mg of heparin subcutaneously on succeeding days resulted in a coagulation time of 20 minutes. The injection of 300 mg on each of two further days produced a coagulation time of 55 minutes, and no subsequent daily dose could prevent fluctuations from 10 to 75 minutes. Doses of both 200 and 300 mg a day for periods of three and four days resulted in the same wide variation.

In Case 21 daily doses of 300 mg for eleven days failed to raise the coagulation time above 18 minutes. In Case 3 alternate daily doses of 200 and 100 mg, given in the penicillin solution, maintained a range of 25 to 35 minutes for eight days, after which the same difficulty was experienced. Later, a daily dose of 150 mg was found satisfactory.

In Case 4 two consecutive daily doses of 100 mg in the penicillin solution gave a coagulation time of 50 minutes. After six days heparin was stopped, and for eight days thereafter the range was 20 to 45 minutes. Resumption of 100 mg a day did not change this finding until a dose of 100 mg was given subcutaneously, resulting in a coagulation time of 65 minutes.

In Case 5 a daily dose of 100 mg in the penicillin solution for twenty-eight days resulted in fluctuations between 30 and 55 minutes, with two readings of 65 minutes. Subsequently 200 mg subcutaneously every other day produced a range of 20 to 38 minutes.

In Case 6 the addition of 100 mg to the penicillin solution produced a capillary coagulation time of 14 minutes, comparable to a venous time of 46 minutes. A reduction of the dosage to 50 mg a day produced a range comparable to 13 to 20 minutes for the first three days. Four days later the range increased to 20 to 25 minutes. Thereafter, a subcutaneous injection of 150 mg daily maintained this range for four days, followed by fluctuations from 20 to 40 minutes. The administration of 200 mg a day by the same route did not alter this range.

In Case 7, as well as in others, a cumulative effect, impossible to foresee, was observed. The addition of 200 mg a day to the penicillin solution produced a range of from 10 to 40 minutes. On the fourth day (without heparin) the time was 65 minutes. Two days later a single dose of 200 mg produced a time of 55 minutes, and thereafter, 100 mg a day held it between 30 and 40 minutes.

In Case 8 the administration of 100 mg daily in the penicillin solution held the coagulation time steadily at 30 minutes, 200 and 100 mg, given subcutaneously on alternate days, produced a range of 20 to 30 minutes. During a subsequent course, 175 mg daily in the penicillin solution produced rapid

fluctuations from 20 to 90 minutes for ten days, after which, without alteration of the dose, the coagulation time remained steady between 40 and 50 minutes.

In Case 9 the addition of 200 mg daily to the penicillin solution was required to produce a range of 20 to 55 minutes, fluctuations between two daily determinations being from 20 to 30 minutes.

When dicumarol was used, an attempt was made to maintain the prothrombin time at 260 to 300 per cent of normal. Daily determinations were made. It was even more difficult to adjust the dose of dicumarol to maintain the desired prothrombin time than to adjust the dose of heparin to maintain the desired coagulation time. As with heparin, considerable variation was found in the individual response to dicumarol. In Case 21 a single dose of 300 mg of dicumarol developed a prothrombin time 2000 per cent of normal, the same patient had failed to obtain the desired response from heparin, even with daily doses of 200 to 400 mg for thirty-three days.

A lag of approximately five days from the initial dose of dicumarol to its full effect was observed in nearly every case. Unless this fact is recognized, the prothrombin time for the first few days may lead to overdose. An initial reduced daily course of 300, 200, 100 and 50 mg respectively for the first four days, followed by 50 mg a day, was finally found likeliest to produce and maintain the desired effect.

The duration of the disease before penicillin therapy combined with anticoagulants ranged from one and a half to fifty-two weeks. In 9 cases this was the initial course of therapy. Of the 15 patients receiving anticoagulants, 8 died, it is only fair to say that 2 patients (Cases 19 and 20) were in extremis when admitted. The duration of the disease before penicillin therapy in patients who did not receive anticoagulants ranged from six to forty-two weeks. Of these 19 patients 3 died with active lesions, 1 died of congestive failure, but was shown histologically to have been cured.

The sensitivity of the causative organism to penicillin in vitro ranged from 0.02 to 1.0 units per cubic centimeter in patients receiving anticoagulants, and from 0.02 to 6.0 units in those who did not. Thus the duration of the disease and the sensitivity of the organism to penicillin covered a wide range in both groups.

EFFECT ON EMBOLISM

When the incidence of major embolic phenomena before and during administration of anticoagulants was analyzed, embolism was found to have occurred before but not during administration in 3 cases, both before and during administration in 3, not before but during administration in 2, and neither before nor during administration in 11. Several patients had more than one course of treatment, permitting multiple observations. Thus, whereas anti-

EFFECT ON RECOVERY

Without regard for any other factors, 4 patients receiving heparin recovered and 4 died. Of the 3

The most significant factor in recovery is not the use of anticoagulants but the daily penicillin dosage. An analysis of the 34 cases in relation to the daily

FIGURE 3 Case 9

The photograph on the left shows the fibrin-covered remnants (A) of the lesion on the mitral valve. The photomicrograph in the middle shows bacteria (A) entwined in fresh fibrin and platelet thrombi (B) attached to the surface of the fibrin, and that on the right, regenerated endocardium (A) overlying organized fibrin (B), as well as bacteria (C) in the mid-portion of the valve with a more densely organized, and apparently older, layer of fibrin (D) beneath.

patients receiving dicumarol alone, 2 recovered and 1 died. Of the 4 who received combinations of heparin and dicumarol, 1 recovered and 3 died. Of 19 patients receiving no anticoagulants, 14 recovered,

penicillin dosage, revealed that with daily dosages of less than 400,000 units combined with anticoagulants 6 patients died and 2 recovered — a ratio of 3:1. With dosages of 400,000 units or over in addi-

FIGURE 4 Case 13

The photograph on the left shows the fibrin-covered fibrous remnant (A) of the mitral valve. The photomicrograph on the right shows bacteria (A) entwined in fibrin overlying calcium.

ered, of the 5 who died, 4 were found at autopsy to have healing but still active lesions, and 1 (Case 12) who died of congestive heart failure was clinically and histologically cured.

tion to anticoagulants, 1 patient died and 5 recovered — a ratio of 1:5. With dosages of 400,000 units or over without anticoagulants, 4 died and 16 recovered — a ratio of 1:4, these cases included

coagulants may have prevented embolism in 3 cases, in 5 they certainly did not

In 2 additional patients (Cases 1 and 13) massive terminal hemorrhage occurred while anticoagulants

produce a cure, therapy with 1,000,000 units a day, in addition to dicumarol, was started. On the third day massive fatal cerebellar hemorrhage occurred. At autopsy the left cerebellar hemisphere was found

FIGURE 1 Cases 1 and 2

The photograph on the left shows the fibrin-covered fibrous remnants of vegetations of the mitral valve (A) in Case 1, and that on the right, the same in Case 2. The photomicrograph in the middle is of the lesion in Case 1, showing bacteria (A) enmeshed in fresh fibrin and a polymorphonuclear reaction (B) in the adjacent fibrin undergoing organization.

were being given. In Case 1 heparin was being used, in Case 13 no anticoagulants were given during eight months of almost continuous penicillin therapy, during which no hemorrhages occurred and only one

to be destroyed, but the valve showed no friable vegetations (see Fig 4). The valve lesion in Case 1 was similar (see Fig 1). Such accidents cannot be dogmatically evaluated in a disease of this nature,

FIGURE 2 Case 6

The photograph on the left shows fresh polypoid vegetations (A) at the root of the pulmonary artery, and that in the middle, fresh cauliflower-like vegetation (A) of the aortic valve. The photomicrograph on the right is of the latter lesion, showing an abundance of fresh fibrin containing myriads of bacteria (A) overlying organizing fibrin (B).

infarction (in the kidney) was observed. After twenty-four days of 1,000,000 and thirty-eight days of 2,000,000 daily units of penicillin had failed to

but the fact remains that these massive hemorrhages did not occur in any of the patients who did not receive anticoagulants.

In Case 12, one of the longest (forty-two weeks) in point of duration of the disease before penicillin therapy, healing of the vegetations took place without the use of anticoagulants. Only a few micro-

organisms remained at the time of the terminal septicemia, it cannot positively be said that the fibrin present at autopsy was not the result of the superimposed staphylococcal invasion. Somewhat comparable

FIGURE 6 Case 17

The photograph on the left shows the fibrin-covered remnants (A) of the lesion on the mitral valve. The photomicrograph on the right shows cocci (A) enmeshed in fibrin, with underlying organizing fibrin and granulation tissue (B).

sclerotic layers of organizing fibrin were found, and no bacteria were present (Fig. 5).

In Case 17, in which the disease lasted twenty-five weeks before penicillin therapy was instituted, death occurred from secondary staphylococcal septicemia

was Case 7, in which the duration of the endocarditis before penicillin therapy was thirty weeks and in which heparin was given for seventeen days and dicumarol for seventeen days because digitalization was necessary, during a

FIGURE 7 Case 7

The photograph on the left shows fibrous pedunculated remnants (A) of the lesion of the mitral valve, which are covered with small patches of fibrin; there is an ulcerative lesion of the auricular wall (B), which also shows scattered areas of fibrin. The photomicrograph on the right shows bacteria (A) enmeshed in fresh fibrin on the surface of the valvular lesion and underlying fibrin (B) in an advanced stage of organization.

No anticoagulants had been used during treatment of the endocarditis. The remnants of the vegetation were small (Fig. 6), and although we believed there was clinical evidence that some fibrin re-

second course of penicillin, dicumarol was given for twenty days. Grossly and microscopically the lesions (Fig. 7) were similar to those in Case 17.

that of the patient (Case 13) described above in whom massive cerebellar hemorrhage occurred. If this case, which is difficult to classify, is omitted the ratio of deaths to recoveries in patients receiving 400,000 units or more daily without the use of anticoagulants is again about 1:5. Ten of the 16 patients who recovered ultimately received from 1,000,000 to 2,000,000 units a day. In 5 cases of recovery with anticoagulants and 400,000 units or over and in 3 of similar dosage without anticoagulants, smaller daily doses had not resulted in cure. Hence, regardless of anticoagulants, the turning point in favor of recovery was the increase in the daily dose of penicillin to 400,000 units or more. Excluding Case 13, because of the fatal cerebellar hemorrhage, there were only 2 deaths in 12 patients receiving 1,000,000 units or more of penicillin a day. One of these patients (Case 21) received anticoagulants, and the

of death and a coagulation time ranging from 10 to 75 minutes had been maintained for nineteen days previously. During the preceding six months penicillin totaling 15,700,000 units had been given. The patient in Case 2 received no anticoagulants. The involved valve of the heart in both cases showed fibrous tags of vegetations covered by a layer of fresh fibrin (Fig 1). In Case 1 bacteria were present in the fibrin and deeper structures, in Case 2 no microscopic sections were made.

Case 6, in which the duration of the disease before penicillin-heparin therapy was almost identical with that of Case 1, had the largest, most typically cauliflower-like and friable vegetations of any of the autopsied patients (Fig 2). Bacteria in large numbers were found in the fibrin, the outer layer of which was fresh. Yet this patient received heparin in daily doses of 50 to 200 mg during twenty-three of the

FIGURE 5 Case 12

The photograph on the right shows a grossly healed mitral valve, with no visible fibrin. The photomicrograph on the right shows one of the few scattered areas of fibrin (A) overlying the almost completely healed valvular lesion, there is a proliferating endocardial cell (B) in the process of covering over the minute area of fibrin.

other did not. The offending organism in the former was an atypical form of *Streptococcus viridans* that was relatively insensitive to penicillin (0.8 unit per cubic centimeter) but sensitive to streptomycin (0.1 unit per cubic centimeter), which could not be obtained until late in the course of the disease. Continuously negative blood cultures could not be obtained, and embolic phenomena continued until streptomycin proved to be the effective antibacterial agent.⁹ This experience is in line with that of most investigators regarding the combined use of sulfonamides and anticoagulants—namely, that anticoagulants are of no avail if the antibacterial agent is ineffective.²⁻⁵

EFFECT ON PATHOLOGIC LESION

Histologically, no conclusive evidence in favor of the use of anticoagulants could be demonstrated. Grossly, Cases 1 and 2 were comparable. In the former the patient was receiving heparin at the time

twenty-five days of penicillin therapy and was heparinized at the time of death.

The disease in Cases 9 and 13 was of about equal duration at the beginning of penicillin therapy (nine and twelve weeks, respectively). The patient in Case 9 received heparin for twelve and dicumarol for seventeen days of the first course of treatment, and dicumarol for nine days of the second course. In Case 13, with a treatment period of eight months, no anticoagulants were administered except during the terminal five days. Grossly and microscopically the lesions were similar (Figs 3 and 4), but if anything there was less fibrin in Case 13. In Case 9 bacteria were present not only in the fresh fibrin covering the remnants of the vegetations but also in the organized and organizing fibrous tissue of the midportion of the valve, three superimposed layers of fibrin, in varying stages of organization and with bacteria between each layer, were present in one of the valve sections, suggesting that heparin during the first course of penicillin did not prevent fibrin formation.

FOREIGN BODIES IN THE RESPIRATORY TRACT*

JOHN R. RICHARDSON, M.D.†

BOSTON

WHEN the diagnosis of foreign body in the respiratory tract has been established by history, physical examination and x-ray study, the surgeon is presented with a problem whose successful solution consists, of course, in the extraction of the foreign body without harm or damage to the patient. Usually, it is the general practitioner who first sees such a patient, and thus the family physician has the first opportunity to make or to miss the diagnosis. Certain pitfalls must be avoided to prevent diagnostic error and improper attempts at removal. This paper briefly reviews some of the salient features of foreign bodies in the various parts of the respiratory tract.

A foreign body in the nose is rare. It is usually self-inserted, and not infrequently the act is concealed by a child. Unilateral nasal discharge in children means that the presence of a foreign body must be ruled out before other possibilities are considered. Within twelve hours after the lodgment of a foreign body in one side of the nose, the secretion becomes purulent. As the days go on, a fetid odor may develop, and over the months and years a rhinolith may form. Bloody nasal discharge occurs immediately after insertion only when the foreign body is sharp and rough. Foreign bodies in the nose are easily seen if looked for. To remove a nasal foreign body, forceps, which often push the foreign body back into the nasopharynx, should not be used; instead, an L-shaped instrument should be employed. If one can get behind a foreign body and pull it forward, it can be readily removed. Cocainization of the nose makes the procedure painless, and adrenalin provides more space by shrinking the turbinates; general anesthesia is seldom necessary. Unless the patient can be absolutely controlled, however, primary general anesthesia is required. The nasopharynx should be guarded, to avoid pushing the object back to be aspirated. Irrigation of the nose often causes ear infection and fails to dislodge the foreign body.

Foreign bodies in the nasopharynx are also infrequent. The patient must cough or gag to drive the foreign body up behind the uvula into the nasopharynx. The symptoms are pain and discomfort referred to the ears, to the back of the head or neck, sometimes to the laryngeal region and sometimes to the cheeks. In other words, unless the nasopharynx can be visualized with a nasopharyngeal mirror, it is unwise to decide that it does not contain a

foreign body. X-ray films demonstrate opaque foreign bodies, such as coins, bones and tacks, but do not show pieces of fruit, nuts or wood. Palpation with the finger is an unsatisfactory method of removal. It should be remembered that if the patient is sitting up, dislodgment of the foreign body may cause it to be lost into the trachea or esophagus or to be pushed forward into the nose. In co-operative adults local anesthesia is quite satisfactory, in children general anesthesia is preferable. The head should be kept low during the operation, and any physician who inspects the results of his adenoidectomies can remove a foreign body from the nasopharynx.

The pharynx and hypopharynx are the most frequent sites for foreign bodies. Ingestion is usually accidental. Because of inability to use the laryngeal mirror, foreign bodies in the hypopharynx are often missed. When the patient complains of pain each time he swallows, a foreign body is present. When there is general soreness that is not made worse by swallowing, the patient has usually suffered only a scratch or abrasion, if the patient gargles a dilute solution of cocaine or pontocaine, the scratch becomes anesthetized and the soreness disappears, but a foreign body such as a bone continues to cause pain on swallowing. This is a simple way to distinguish between an abrasion of the pharynx or hypopharynx and the actual presence of a foreign body. Unless the hypopharynx is carefully inspected with the laryngeal mirror, a foreign body may not be found. The roentgenologist has difficulty in seeing small fishbones imbedded in the base of the tongue or at the bottom of the tonsillar fossa; these are clearly visible with the laryngeal mirror. Once a foreign body has been seen in the pharynx or hypopharynx, hasty grasping must be avoided, since a fumble means its loss. Often, three hands are required for a successful extraction, — one hand for the patient's tongue, one for the laryngeal mirror and one for the forceps used to grasp the bone, — and sometimes an additional pair of hands is needed to hold the patient's head. An example is afforded by a case in which an attempt to grasp, by means of a tongue depressor and a hemostat, a pin visible in the pharynx caused the pin to land in the tracheo-bronchial tree, where, of course, the problem was much more difficult than the one presented by the pin at its original site. In another case, which emphasizes the fact that more harm than good can be done by working under adverse circumstances, a sixteen-month-old baby was seen by its mother to cough and choke after having placed something in its mouth. A physician who examined the child be-

SUMMARY AND CONCLUSIONS

Thirty-four consecutive and unselected cases of subacute bacterial endocarditis treated with penicillin constitute the material for this report. Twelve patients received anticoagulants from the outset of penicillin therapy and also during subsequent courses when more than one course of treatment was given. Two, who were admitted in advanced stages of congestive cardiac failure after varying periods of penicillin therapy without anticoagulants, died after combined penicillin and heparin therapy lasting nine and eight days respectively. One, previously treated for eight months without anticoagulants, suffered massive cerebellar hemorrhage three days after a course of penicillin combined with dicumarol had been begun. Nineteen patients were treated without anticoagulants at any time.

Death occurred in 12 cases in the entire series, and autopsy was performed in 10. There were 4 deaths among the patients who received anticoagulants from the outset of therapy, and 4 among those who received anticoagulants twelve, nine, eight and five days, respectively, at the end of long periods of penicillin therapy. There were 4 fatal cases in which no anticoagulants were given. In 1 of these the patient was histologically cured but died of congestive heart failure. The ratio of deaths to recoveries in patients receiving less than 400,000 units of penicillin—all of whom received anticoagulants at some time—was 3:1. The ratio in patients daily receiving 400,000 units or more of penicillin was 2:5 when anticoagulants were used throughout or during part of the therapy, whereas on a similar schedule, the ratio was 1:5 in patients treated without anticoagulants at any time.

In 5 cases anticoagulants failed to prevent major embolism, in 3 prevention was possibly obtained by this means, and in 11 no major embolic phenomena were observed before or during the use of anticoagulants. Of the 19 patients treated without anticoagulants at any time, 6 had major embolism and 13 did not.

We could find no way of determining whether anticoagulants prevented further clotting at the site of embolism.¹⁰

Gross and microscopic specimens from patients treated with and without anticoagulants are presented. The most typically polypoid and cauliflower vegetations were found in a patient who died at the end of twenty-five days of combined penicillin and heparin therapy. An abundance of fresh fibrin was present on the vegetations. The most nearly complete stage of healing was present in a patient who did not receive anticoagulants. All other lesions showed advanced stages of healing, and yet all showed some fresh fibrin on the surface. The amount

of fresh fibrin present on the lesions in patients treated with anticoagulants was not demonstrably less than that on the lesions in untreated patients.

Generally speaking, thrombosis at the site of the intravenous needle was less in the patients receiving heparin incorporated in the penicillin saline mixture. Small amounts of heparin (50 mg) added to the mixture when the preferable intravenous drip method of administration is used, may aid in retarding venous thrombosis.

Since considerable variation in response to the same dose of heparin or dicumarol was found in the same and in different patients, no standardization of dosage was possible.

No statistical, anatomic or histologic evidence could be found that anticoagulants are a necessary adjunct to penicillin therapy of subacute bacterial endocarditis.

If the daily dose of penicillin is adequate and treatment is continued long enough, healing of the vegetations will take place as well without as with anticoagulants. The rate of recovery was 100 per cent in our latest 15 consecutive cases, in most of which the patients daily received 1,000,000 units or more. All these patients were treated without the use of anticoagulants.

It is doubtful that anticoagulants prevent major embolism.

Fatal hemorrhage resulting from the use of anticoagulants was suggested, although not proved, in 2 of the cases.

The additional cost, which is large when heparin is used, as well as the expense and inconvenience to the patient of daily determinations of coagulation or prothrombin time, does not seem justified.

We are indebted to Dr. Eugene Hildebrand for his assistance in evaluating the gross and microscopic lesions.

tion, however, the outlet closes as the bronchus constricts, and air trapping distal to the foreign body develops. This is emphysema. When the foreign body has been in place long enough to block the bronchus completely, the emphysematous air distal to the foreign body is slowly absorbed, and collapse of that segment of the lung occurs. Expiration and inspiration films are a substitute for fluoroscopy. Fluoroscopic examination of a patient suspected of a foreign body in the bronchus is always indicated, because it is often difficult for the x-ray technician to obtain full expiration and inspiration films. On expiration, air leaves the one but not the other lung, which remains full and demonstrates air trapping in the main bronchus. Such expiration and inspiration films are diagnostic of a nonradiopaque foreign body in the main bronchus. Without bronchial obstruction a foreign body can be in place for a long time without infection. A pin, for example, may remain for years in the lung without causing trouble unless it perforates a vessel or creates granulations that block a

bronchus. It is bronchial obstruction that causes harm and permits infection to become rampant.

* * *

The diagnosis of a foreign body in the respiratory tract is easy when one remembers to think of the possibility. The story of the patient or that of the patient's family should be believed until proved wrong. X-ray examination should include the entire respiratory and digestive tracts. Fluoroscopy of the chest is indicated when a nonradiopaque foreign body is suspected. Unless a foreign body can be completely visualized, it is dangerous to attempt its extraction. The safe removal of a foreign body is aided by the possession of a duplicate, as well as x-ray study, so that its exact position and location are understood. Only then can removal be accomplished without the possibility of doing more harm than good through unwise manipulation. Extractions of foreign bodies are best done where there is an adequate armamentarium to deal with any complication that may arise.

BOSTON MEDICAL LIBRARY

Report of the President*

THIS annual meeting marks the end of my five-year tenure of the office of president, the first two having comprised the unexpired term of my predecessor and the last three the regular term prescribed by the by-laws. Since I could not accept renomination if it were offered, it is appropriate that I should render a brief account of my stewardship, with special reference to the state of the Library and to plans that are under consideration for its future.

First, I ask you to pay silent tribute to the following eight fellows who died during the year: Hugh Cabot, Charles H. Lawrence, Jr., Charles T. Porter, Abraham Rudy, Philemon E. Truesdale, Hugh Williams, Robert S. Hurlbut and Robert Sanderson. Worthy of note as examples of long-continued, loyal support are the forty-seven-year and forty-two-year memberships, respectively, of Dr. Cabot and of Dr. Truesdale. In this connection I am reminded of a physician who would not wish his identity to be known who, at the age of eighty-three and a fellow for many years and long retired from practice, submitted his resignation, on learning of our financial needs, however, he withdrew the resignation and doubled the amount of his annual dues.

Secondly, I have the privilege of making grateful acknowledgment, personally and on behalf of the Library, to the trustees and executive officers who have served with me, to the resident staff and to individuals and organizations who have continued

their loyal support. The Trustees, although they are busy with public and personal obligations, have served on committees and pooled their wisdom for our benefit, our secretary, our treasurer and above all our librarian have discharged their duties with no compensation except that of an approving conscience, and our resident staff, depleted in numbers, overworked and perhaps underpaid, under the directorship of Mr. James F. Ballard (now in the fifty-fourth year of his service) have serviced our collections and, so far as humanly possible, adequately met the needs of readers, students and researchers. The Massachusetts Medical Society, whose organ, the *New England Journal of Medicine*, is edited on our premises, and whose executive officers and committees share our building, brings us prestige and support in return for our services and help, likewise the *Journal of Bone and Joint Surgery* and many special societies make use of our facilities to our mutual advantage.

The last five years comprise the entire period of the participation of our country in World War II, together with the months of disruption of normal peaceful activities immediately preceding and succeeding it. Perhaps a total world war is sufficient excuse for any enterprise such as ours not only to fail to advance but also to develop structural and functional weaknesses. Friends of the Library who have read the reports of the president and of the librarian for the last four years are familiar with the matters that have preoccupied us, among which are the conversion of our heating system from oil

*Presented in part at the annual meeting of the Boston Medical Library March 5, 1946.

heaved that there was a wheel from a plastic toy lodged in the hypopharynx and therefore suggested sending the child to the hospital for removal. The mother demurred and called a second physician, who said that with a tongue depressor he could see a disklike object in the hypopharynx that could be grasped with the fingers but could not be dislodged. After unsuccessful efforts for an hour with a can of ether, a flashlight, a tongue depressor and the fingers, the child was taken to the Massachusetts Eye and Ear Infirmary, where a laryngoscope and forceps were requested, to remove the disk, which had some sort of protrusion on its inferior surface. X-ray films were taken in spite of the fact that the physician considered them unnecessary. The films demonstrated the eye of a toy bear imbedded, with the large end in the hypopharynx and the pointed portion, used to hold the eye in the bear, penetrating the pharyngeal wall and extending down into the soft tissues of the neck. In the pharynx above the eye, a laceration about 2.5 cm long and 0.6 cm wide was observed. Manipulation had resulted in a tremendous amount of air emphysema in the soft tissues of the neck, this extended into the mediastinum around the heart and up to the base of the skull. After extraction of the foreign body and the administration of penicillin and sulfadiazine the patient made an uneventful recovery. This case emphasizes the value of x-ray examination and the fact that extreme caution must be observed in manipulating a foreign body.

A foreign body in the larynx is rare. If a foreign body of any appreciable size lodges in the larynx, the airway is obstructed and the patient dies promptly, before help can be given. The object, however, may be small enough so that the patient can breathe around it, but whenever a foreign body prevents the vocal cords from approximating normally, hoarseness results. It is too often forgotten that hoarseness means trouble with the organ of speech, the larynx. A case in point is that of a twelve-month-old child with a history of increasing cough and hoarseness of four weeks' duration in which x-ray examination demonstrated a safety pin between the vocal cords. It was apparent from these films that the pin was pointed up and that the point was imbedded anteriorly in the base of the epiglottis. When I saw this x-ray film, I doubted the mother's statement of four weeks of hoarseness. The larynx was exposed without anesthesia, and it was seen that the blackened, corroded head of a safety pin in the posterior portion of the glottis was almost completely surrounded by red granulation tissue. I attempted to remove this pin by grasping the head and holding the point with the tip of the laryngoscope. After carrying out this procedure, I discovered that I had the head and the back of the safety pin, but that the spring and the pointed end were missing. Inspection of the larynx did not reveal the remainder of the pin. The child was taken

to the x-ray room, where films demonstrated the remainder of the pin in the right main bronchus. A bronchoscope was inserted, and the portion readily removed. The corrosion and brittleness of the pin offered sufficient proof that the mother's statement regarding the four weeks' duration was reliable. Without the x-ray examination and many pieces of equipment, this case might have been difficult. Thus, it is essential that the removal of any foreign body from the larynx or below be done in a hospital equipped to deal not only with the particular situation but also with all possible complications.

Foreign bodies in the trachea challenge diagnostic ability, unless they are radiopaque, when they are easily diagnosed by x-ray examination. But the diagnosis of a nonradiopaque foreign body in the trachea is made by the history and physical signs. Even in the youngest children, the pathognomonic signs are a sudden stopping of the expiratory air blast, with cessation of phonation and paroxysmal cough, followed by relief with a good airway and good phonation. Large seeds or shells of nuts produce these signs. Recently, a three-year-old child coughed and choked when he fell while eating. He was taken to another hospital, where a variety of studies, including x-ray films, were carried out. He was discharged and then returned to the hospital for a stay of another week. Periodically he had attacks of cyanosis associated with coughing and wheezing, and because of one of these he was rushed to the Massachusetts Eye and Ear Infirmary for an emergency tracheotomy. On arrival, the signs had subsided. Shortly after admission, they recurred and then disappeared. A large piece of pistachio-nut shell was removed from the trachea through a 5-mm bronchoscope, and the child was subsequently symptom free.

Foreign bodies that are aspirated usually do not move up and down in the trachea but become lodged in one of the main bronchi or, if small, go farther into one of the smaller bronchi. It is not so much the actual diagnosis of foreign body in the bronchus that is difficult as it is the consideration of the possibility. The physician not only forgets to ask about the possibility of a foreign body but also, too often, fails to believe the patient's own story. An x-ray film, which is easy to take and inexpensive, often explains an atypical case of pulmonary disease. The physical signs of bronchial obstruction are well known. In time, bronchial obstruction leads to suppuration, with fever, chills, cough and sputum. Although an x-ray film of the chest leaves no doubt that a radiopaque foreign body is present, it is equally effective in revealing nonradiopaque objects that have been in place for a long time. If a foreign body causes only narrowing of the bronchial lumen, a wheeze is the cardinal sign. Irritation of the bronchial tissues by a foreign body results in swelling and a further narrowing of the lumen so that air passes the foreign body on inspiration, with dilation of the bronchus, on expira-

Society and by various committees and other groups. At present the Society's executive offices and the editorial rooms of the *New England Journal of Medicine* are in our building, an arrangement that contributes much to the efficiency and prestige of both.

The exact nature of the proposed alliance will require careful study. Many of the older fellows would be sorry if the Library lost anything of its distinguished identity, a misfortune that could not occur to the Society. The Library has assets valued at between one and two million dollars, depending on the appraisal of irreplaceable files and memorabilia. It is a corporation, and the title of its property is vested in the fellows, who constitute the corporation and whose dues are an important source of income. Nearly all the fellows of the Library are members of the Society but about four fifths of the latter are not fellows of the Library, although they would be perfectly eligible if they so desired after the formality of proposal for membership and action by the Committee on Elections had been complied with. If the Society wished to make a substantial annual contribution to the support of the Library, the comparative status of members of one and fellows of the other would require definition and adjustment. As a matter of fact, the Library has always extended a warm welcome to all reputable

physicians — indeed to all citizens — to use freely its facilities and enjoy its privileges, except only those necessarily pertaining to actual ownership or to its status as trustee under wills and bequests.

This is not the place to elaborate on the legal and practical problems raised by this plan. If its realization seems wise, these problems can be solved by men of good will. The broad and liberal view seems to be that we have two organizations whose purposes are essentially identical in striving to promote the public health, each with an enviable record of unselfish service over many years. One has a plant and collections of stored medical knowledge second to but few in this country but lacks endowment and other income adequate for its support, the other, through its numerical strength and wide influence, is able to contribute that support. As one who for nearly forty-five years has been active in the affairs of both these organizations and who has the deep conviction that the prestige and strength of each would be promoted by a close alliance, I have no hesitation in urging that its feasibility be explored to the end that its consummation be accomplished at the earliest possible moment, for time is of the essence now that, after the disruption of War, the institutes of peace are to be restored.

DAVID CHEEVER

Report of the Librarian*

WITH the end of the war and the return of men from the services, the Boston Medical Library is slowly regaining the position it held five years ago. By the beginning of 1946 the membership had already increased and had reached a total higher than that at any time in the history of the Library. During the year, the staff remained unchanged and the Library continued to function at a decreased pace but serving its clientele in what appears to have been a reasonably satisfactory manner. At least no major complaints were heard by the librarian and although many of our services were, of necessity, restricted and we were cut off almost entirely from foreign medical literature, books as well as periodicals, we extended our holdings in English-language periodicals and made an attempt to keep abreast of the times. Much of our foreign-language material, which is being stored abroad, will presumably be made available to our readers in 1946. The German material is entirely lost, but it is quite possible that the paper on which it was printed was so inferior that binding would not have been advisable, these missing periodicals may now be reprinted or duplicated in some form on better paper so that they will have a chance of survival.

The librarian thought the time fitting to give a brief review of the various departments of the Library, covering a period of ten or more years. A discussion and tables on periodicals, binding, membership, use of the Library and size of the Library are therefore included in this report, in addition to the usual departments of book reviews, publications and a statistical evaluation of the contents of the Library as of December 31, 1945.

THE LIBRARY FROM 1936 TO 1945

Periodicals

The current medical literature is largely in periodical form, and the greatest use of a library such as ours is found in this department. The total number of periodicals received in 1945 was 578, only 44 being in languages other than English. Our average from 1930 to 1940, before the war, was about 800 to 900, in 1930, for example, we received 870, and 410 (nearly 50 per cent) were in foreign languages. Since about 1937, by arrangement with the Harvard Medical School Library, we have specialized in clinical journals. It, in turn, has expanded into the fields of public health, dentistry, biology, basic sciences and ophthalmology (Howe Library). This collaborative effort reduced our total number of

*Presented in part at the annual meeting of the Boston Medical Library March 5 1946.

to steam, structural alterations to meet the needs of the Massachusetts Medical Society and the *Journal of Bone and Joint Surgery*, the establishment of the James F. Ballard Publication Fund, the issue of a catalogue of our incunabula and manuscripts and the promotion of an elaborate survey of the various medical libraries in Boston. But also since the beginning of the administration of my predecessor, or for at least twelve years, your officers have been anxiously occupied with the problem of conducting a dynamic and expanding enterprise under the handicap of originally inadequate and steadily diminishing financial resources. The Library, ranking second or third in the United States in the value of its collections and the potential importance of its services, is conducted with heart-breaking economy on a yearly income of about \$30,000. It should have resources of at least double that amount, together with a corresponding capital sum for completing and improving our still unfinished house. We are seriously in arrears in the purchase of current texts, in subscriptions to periodicals, in binding and rebinding and in cataloguing, and there is literally no room for accessions except temporary installations in the basement and corridors. Only the invincible optimism of our librarian, Dr. Viets, and the efficient industry of Mr. Ballard and his staff have kept up our courage and maintained the library service so well that there have been scarcely any complaints. The details of our physical condition have been so well presented in previous reports that they may be omitted here.

It is the almost unanimous opinion of your officers and their advisers that the provision of facilities for the collection, housing, circulation and preservation of the literature of the medical and allied sciences in any geographic area should be conceived on broad principles of co-operation and mutual assistance among the various interests involved, instead of the individualistic development of a number of essentially similar units all situated within a mile or two of each other. At the turn of the century, when ours was the only considerable collection in this vicinity, it seemed reasonable that the library should continue its independent career, supported by bequests and gifts and by its fellows and members. Later, a plan to build about it as a nucleus an elaborate academy of medicine, enthusiastically advocated by a group who went so far as to secure an option on land and to obtain an architect's services, was reluctantly given up because of the expense involved, which ran into millions of dollars. During this time there came into being the working libraries of Boston University, Harvard and Tufts College medical schools, as well as the libraries of several major hospitals and numberless small collections of individual investigators and teachers, one of these is well known actually to rival our library in size and usefulness. The survey and resulting plan, designated by us as the "Fleming-Metcalf Plan," which

aimed to integrate and develop these elements into a co-operative and mutually beneficial system, has been approved by the authorities of the three medical schools and its consummation actively pressed by your officers. Briefly, the plan envisaged the gift of a large sum by a charitable foundation for capital expenditure, the raising by the Library of a similar sum by subscription among the medical profession and other friends for endowment and the contribution annually of substantial contributions by the working libraries of medical schools and hospitals in return for our service as a central reference and research library ready to supply the needs of the smaller units beyond those of the everyday requirements of faculty, students and staff, and to make unnecessary the expensive enlargement of their physical plants. This plan had the invaluable support of Mr. Metcalf, Director of Libraries of Harvard University, and the tentative approval of the administrators of the three medical schools. Unfortunately, the members of the foundation, although approached by one who had their ear, found themselves unable to embrace the opportunity. Several other sources were unresponsive. Your officers and committees reluctantly concluded that without this aid the project as planned could not be realized.

Another plan is now under consideration—one that for some years has been tentatively suggested and as often put aside as possibly presenting peculiar difficulties. It is nothing less than a proposal of honorable marriage to a contemporary of the Library, quite similar in age, outlook and ambition for future accomplishment. Perhaps, since the prosecution of this suit must rest in the capable hands of my successor, I should not mention it, but after all I have sat in at preliminary talks among the old folks and it is well that the community should get used to the idea.

The Boston Medical Library and the Massachusetts Medical Society have much in common. Perennially young though they may be in spirit, they are perhaps the oldest of their kind in the country, if we date the former from the Second Social or Boston Medical Library, organized in 1803 by the Medical Improvement Society, under a statute of 1798. The statements of their aims as inscribed on their charters are practically identical. The fellows of the Library are almost without exception members of the Society. In 1876, when the Library moved from its two rooms in a basement in Hamilton Place, furnished with two tables, thirteen chairs and some bookshelves, to a little remodeled house at 19 Boylston Place, among the distinguished speakers at the dedication ceremonies was Dr. George H. Lyman, president of the Society. Soon the books accumulated by the Society—1500 in number—were turned over to the Library. Almost from the first the Council of the Society met in the meeting hall, followed by the Suffolk District Medical

from 17 in 1944 to 31 in 1945, is directly attributable to the energetic work of the Membership Committee.

SPECIAL ACCESSIONS

As usual our restricted funds for special types of books were expended for the purposes designated

to be diverted into channels other than the more frequent one of acquiring the latest texts and monographs. This we also do, so far as our income permits. More funds are urgently needed for current literature, and until we have them some fields of medical advance will not be fully covered by our accessions. We are relatively strong in our chosen

FIGURE 1 Title Page of *Les simulachres & histories faces de la mort*, by Hans Holbein (Lyon, 1538)

by the various donors. That a considerable portion of our book funds are so entailed leads to a belief that the Library is primarily an antiquarian institution, with little interest in current medical literature. This is not the case, although we are particularly fortunate in having more funds than most libraries

field, clinical medicine, and by co-operation with other libraries all fields are fairly well covered in the Boston area. In the special groups, however, we have continued to buy a considerable number of important books, and in some cases to catalogue previous purchases.

periodicals by about 100. During the war, with most of the foreign journals omitted, the number fell as low as 466 in 1944. In 1945 the number of periodicals increased to 578, without most of the more than 400 foreign journals previously received. We have some reason to suppose that our back files of foreign-language journals, except for the German periodicals, are intact in Europe and awaiting shipment to Boston. Our stock of German journals was probably lost by bombing. According to our latest information, the French, Italian, Dutch and Scandinavian periodicals are awaiting clearance and shipping space. Russian journals are now arriving in good number by way of exchange. When we know the cost of our foreign-language stock now abroad, we shall again ask aid from the special societies, which have made generous donations in the past for this purpose.

About 150 journals come to us each year from the *New England Journal of Medicine*, received by them in exchange. When the paper shortage is less and a greater number of issues of the *Journal* can be printed, this list may be expected to increase. The Library could use 50 or more subscriptions of the *Journal* to advantage, and the editor, as always, extends a generous hand in our direction.

Binding of Periodicals

Until about 1937 the Library bound nearly all the periodicals received each year—a total of approximately 900 volumes. Since that date we have had to curtail this activity for financial reasons and now only bind in permanent form 50 to 60 per cent, the others going into temporary binders. Thus, in 1945, only 360 of the 578 periodicals received could be bound. This is naturally disturbing to the librarian, and although it does not preclude the use of these journals, a backlog of journals requiring binding is being built up that we can hardly afford, if the Library is to remain in a workable condition. Since the periodical files are used more than any other division of the Library, permanent binding is almost essential.

Size of the Library

The number of books in the Library slowly approaches 200,000, a total of 199,135 being reached in 1945. The collection of pamphlets, numbering 135,195, grows only gradually, since reprints of papers occurring in the current literature are no longer catalogued. Nearly 3000 books, including 700 bound volumes of periodicals, and over 1000 pamphlets were added in 1945. To catalogue these items, more than 10,000 cards were used.

Plans must shortly be made to provide additional space for our growing collections. This could be done in a number of ways. We have room in our own building for seven more tiers of stacks, which should be built, if funds could be found, for this would be a natural way to house our collection. Secondly,

we might transfer the 10 to 20 per cent of our collection that is seldom used to the Harvard University Deposit Library. The cost of storage is relatively low, and items so stored can be removed for use in the Library in a few hours. Thirdly, if a new library is provided in the near future for the Army Medical Library in Washington and it is allowed to become a national medical library, with appropriate borrowing privileges extended to us, we might take from our shelves certain rarely used material, particularly in the nonclinical sections, and deposit it in Washington.

All these plans have good features, and some use of each is probably the best method of handling the problem. By 1950 the librarian hopes to see the stacks completed, some of our collection transferred to the Harvard University Deposit Library, our basement cleared of duplicates and our arrears dissolved. If someone will give us the tools, in the form of funds, the staff, augmented by new personnel, will do the job.

Use of the Library

Both the circulation—that is, the number of items taken from the shelves for use by readers—and the attendance increased in 1945 over 1944, the former from 29,949 to 31,298 and the latter from 7021 to 7100. The circulation in 1945 was approximately that of the average for the last ten years, but we have had during this period, for some reason not fully explainable, a wide swing from about 25,000 to 47,000. The attendance in 1945 was only about 70 per cent of its normal level of 10,000 a year, but it is expected that, with members rapidly being demobilized, the number will rapidly increase. If 10,000 readers use 35,000 items in a year, the Library, as now constituted, is giving a reasonable service. The space for reading in Holmes Hall and elsewhere is rarely used to its limit, since most members call for books and periodicals to use at home or in the office. About 7 out of 10 readers using Holmes Hall are nonmembers.

Membership

The total membership in the Library rose to a new height in 1945, the figure being 932. Fellows constitute about 70 per cent of this total. We have been slowly increasing our membership since 1930, particularly in the years since 1937. There is nothing artificial about our growth, and the increase in numbers indicates a healthy condition, in spite of our numerous and indeed obvious weaknesses. It is hardly a sign of decadence when an increasing number of doctors find it profitable to use the Library and to pay for doing so. The growth speaks well, moreover, for the continued success of the active Membership Committee, but I doubt if even they could hold the membership to its present level if the Library did not offer a reasonably good service. The large increase in the professional members,

in 1507, and a third, in 1517, was particularly grave in Oxford and Cambridge. In 1528 another epidemic occurred in London, driving the court of Henry VIII from his residence. From England it spread to Europe, first to Hamburg and then into France and Italy. The so-called "English sweat" never appeared in Europe thereafter, but an epidemic in England, in 1551, was described by John Canus in his famous book published in 1552.

The Library added an account of this disease published within two years of the Hamburg outbreak, which began on July 25, 1529. Joachim Schiller, born at Herdern, near Freiburg, was in practice when he published, in 1531, *De Peste Britannica* (Fig. 3). The European epidemic ended in Novem-

ber, 1501, a treatise on syphilis entitled *Malum Francie*, which has been acquired by the Library. He was, of course, writing from Ulm, in Germany, and used the common appellation of the time. His book, published in Hagenau, appears to be rare, since only one other copy is recorded, in the library at Zwickau (at least it was so noted before World War II). It is interesting that the manuscript from the Ulm physician crossed the Rhine to be printed in Hagenau by Heinrich Gran, a well known printer of fifteen-century medical books. The syphilis tract is a brief account of five pages.

Hugo Senensis (Ugo da Siena) was one of the most prolific of the medical writers of Italy. He taught at Siena, Bologna, Parma and Pavia and gave lectures at the Sorbonne. One of the earliest physicians to write in the common tongue, his *Trattato* is a justly celebrated incunabula, first printed at Milan in 1481. The original edition is in the Library (No. 383 in the Ballard catalogue³). A later printing (Milan, 1508) in Latin was added to the Library in 1945, with an interesting woodcut on the title-page depicting doctors and astrologers in consultation (Fig. 4).

English Imprints

Seven books, printed in London before 1640, were added. One was a partially recorded early printing, probably the first edition, of a work by J. Fletcher entitled *The Differences, Causes, and Judgments of Urine* (Cambridge, 1598). There is an imperfect copy in the library at Cambridge, England.

Spanish Imprints

Nine books were added to this class, including a treatise on physiology written by the Mexican, M. J. Salgado, in 1727.

Americana

Of particular interest are the *Armory Square Hospital Gazette*, published by a Washington hospital in 1864-1865, the *Medical Inquirer*, a botanic journal issued in Fall River and Middleboro in 1846-1847, Joseph Warren's 1772 and 1775 "Oration" and an engraved card, "Entitles to Kine Pock Inoculation," signed by Benjamin Waterhouse.

Modern Manuscripts

The *Letter Books* of Julius Griffiths, in four volumes (1810-1829), and the *Records of the Rutland County Medical Society*, 1816-1829 (Rutland, Vermont) were added.

Incunabula

Three incunabula were added, two of which are not recorded in the Stillwell *Second Census*: the *Commentaria in Platonem*, by Marsilius Ficinus (Florence, 1496), and the *Quaestiones Naturales* (Cologne, circa 1500).

FIGURE 3 Title Page of *De Peste Britannica*, by Joachim Schiller (Basle, 1531)

ber, 1529, apparently as rapidly as it had begun. Schiller's work, a pamphlet of twenty-five leaves, is a scholarly discussion of the disease, without much historical importance. He gives no real description of the epidemic of 1529.

Otto Raut, an astrologer, who issued a prognostication for the years 1502 and 1503, also wrote,

Sixteenth-Century Imprints

Among the foreign imprints of the sixteenth century, we have acquired *Les simulachres & historiees faces de la mort* by Hans Holbein (Fig 1). This book, the first edition of Holbein's *Dance of Death*, was published in Lyons in 1538. It is illustrated with forty-one small woodcuts, as fine as copper plates, probably made from Holbein's drawings by Hans

Often reproduced in medical literature is the drawing of the skeleton, Death, calling on the physician in his study (Fig 2). Beside the doctor lies his dog. Death leads in an elderly, sick man for consultation with the physician, bringing the urine bottle for casting. The sharp-nosed doctor is not perhaps our ideal physician, but he is obviously a student and the old man, the patient, is a figure

FIGURE 2 Holbein's Drawing of the Physician, Death and an Elderly Patient in the First Edition of *Les simulachres & historiees faces de la mort* (Lyons, 1538)

Lützelburger Warthin,¹ who describes the book in detail, although with a number of errors, states that more than a hundred editions, as well as copies and imitations, are known, following this first printing in book form in 1538. The *Totentanz* or *dance macabre* was a favorite subject for the Renaissance illustrators, and Holbein's figures, or imitations of them, occur frequently as initial letters in books of the sixteenth century

of great charm. Warthin describes Holbein's technique as follows:

In the Holbein cycle the art of the *Totentanz* motive reached the highest point of its development. Nothing has since approached it, either in inspirational value, human interest, or in skill of technique.

The sweating sickness, a fatal epidemic disease running a rapid course, first appeared in England in 1485.² A second, less severe epidemic was noted

Miscellaneous

There were no staff changes in 1945, our six regular employees continuing to give the best service possible under restricted conditions. Ten, or possibly twelve, people are needed to run the Library in a satisfactory manner.

The Massachusetts Medical Society, the Boston Society of Psychiatry and Neurology, the Suffolk District Medical Society, the New England Heart Association, the Boston Surgical Society and the Boston Medical History Club met, as usual, in the Library.

Our cordial relations with our close associates in the building, the Massachusetts Medical Society, the *New England Journal of Medicine* and the *Journal of Bone and Joint Surgery*, were maintained.

The director and the librarian attended meetings of the honorary consultants of the Army Medical Library, Washington, D C, and the librarian delivered an address at the dedication of the Ditttrick Museum in the Cleveland Medical Library on October 6, 1945.

MEDICAL PROGRESS

DISEASES OF THE THYROID GLAND*

SAMUEL L GARGILL, M D,† AND MARK FALCON LESSES, M D‡

BOSTON

SINCE 1942, when the last review of this subject appeared in the *Journal*,¹ there have been many important advances in the understanding of the biochemistry and physiology of the thyroid gland. In addition, a new group of substances that are goitrogenic and at the same time markedly depress thyroid function have been extensively investigated. Radio-iodine, which has been widely used in the investigation of thyroid physiology and iodine metabolism, has reached the stage of clinical usefulness in the treatment of toxic goiter. The value of blood iodine studies continues to be demonstrated, with chief emphasis on the protein-bound iodine of the serum. Finally, there has been further study of the cause of exophthalmos in animals, as well as some clarification of the clinical problem involved.

THE THYROID HORMONE

The diverse actions of the thyroid hormone on bodily functions are fairly well known, but the

exact chemical nature of the hormone and the mechanism of its biosynthesis have not been completely elucidated. It has been established that the hormone itself lies somewhere between the large molecule protein, thyroglobulin, and the relatively simple, iodine-containing amino acid, thyroxine, if in fact it is not either. Harington² has contributed new evidence that favors the view that the circulating or effective form of the hormone is thyroxine. It has long been accepted that thyroxine produces every symptom of clinical hyperthyroidism except exophthalmos and conversely is capable of relieving every symptom of myxedema, whether clinical or experimental. It has not been possible, however, to demonstrate a direct effect of thyroxine on normal surviving tissues in acute experiments of several hours' duration. Craig and Salter³ believe that the thyroid hormone is not thyroxine because of the failure of thyroxine, when added to normal blood, to induce the calorigenic action in excised surviving tissues that was readily produced by the blood of thyroxinized animal. The authors themselves remark on the high degree of variability in their data but consider their conclusions statistically valid. In addition, the physiologic activity of the thyroid

Book Reviews

Owing in part to the fact that many of our regular reviewers were still in the service, only forty of the

Exhibits

During 1946, the following exhibits were set up in the entrance lobby of the Library

Röntgen, Konrad In commemoration of the fiftieth anniversary of the discourse of the x-ray (November 8, 1895)

FIGURE 4 Title Page of *Tractato Utilissimo circolo Regimento e conservatio de la Sanitade*, by Hugo Senensis (Milan, 1508)

two hundred and twenty-six books received from the *Journal* in 1945 were given extended review notices. The other hundred and eighty-six were allotted short reviews or summaries. Eighty-three reviewers, whose names are listed in the two annual index numbers of the *Journal*, gave a valuable service to the Library. Mr. Ballard, as in the past, carried the brunt of the work on the short notices.

Dürer, Albrecht An exhibition of five editions of his book *Human Proportion*, including the first edition (Nuremberg, 1528).
Cornwall, Dean Series of paintings of outstanding American medical events.

Publications

Recent articles emanating from the Library are as follows

workers¹⁹ have repeatedly shown that with tracer doses almost all the radio-iodine deposited in the thyroid gland is organically bound within an hour.

When large amounts of radioactive iodine are added to the medium in which surviving thyroid tissue slices are respiring, there is rapid incorporation of the radio-iodine in the tissue. As in the experiments *in vivo*, the radioactivity is first associated with di-iodotyrosine and later appears with thyroxine, indicating the same process of conversion as in the intact animal.^{21, 22} It is of interest, however, that Schachner, Franklin and Chaikoff²³ demonstrated that surviving thyroid slices were able to concentrate up to 60 per cent of added radio-iodine even after the inhibition of thyroxine and di-iodotyrosine formation by azide or sulfanilamide. Cyanide and sulfide, in addition to inhibiting thyroxine and di-iodotyrosine formation, blocked the accumulation of radio-iodine by thyroid slices. From this selective blocking of iodine concentration and thyroxine formation, the authors concluded that thyroid tissue possesses a mechanism for concentrating iodine that does not depend on conversion of inorganic iodide to thyroxine and di-iodotyrosine.

This group of investigators²⁴ has directed attention to the importance of an enzyme system in the biosynthesis of thyroxine, first by demonstrating that homogenized thyroid tissue has lost its capacity to incorporate radioiodine, thus proving the need for cellular organization, secondly, by showing that the incorporation does not occur with complete anaerobiosis, and thirdly by blocking di-iodotyrosine and thyroxine formation from inorganic iodide in thyroid slices by typical inhibitors of cytochrome oxidase, such as cyanide, azide, sulfide and carbon monoxide. Dempsey²⁵ has demonstrated the presence of cytochrome oxidase in the cells of the thyroid follicle and has also presented evidence for the presence of peroxidase in the thyroid cells. He found that the peroxidase reaction was easily inhibited by thiouracil, whereas the cytochrome oxidase reaction was unaffected. This has been confirmed by DeRobertis and Grasso²⁶ regarding peroxidase activity and the inhibitory effect of thiourea.

Harrington and Pitt Rivers¹⁵ postulate that the enzymic oxidizing system liberates iodine from iodides and this free iodine is the effective oxidizing agent that both converts tyrosine to di-iodotyrosine and vice versa. Keston²⁷ lends support to this view by the demonstration that iodine and oxidases participate in the reaction that organically binds iodine. Recently, Remeke and Turner²⁸ after a study of the factors influencing the iodination of casein, concluded that manganese is probably also an important catalyst that acts in promoting thyroxine formation *in vivo*. Ray and Deysach²⁹ had earlier shown the particular ability of the thyroid to store manganese. The biosynthesis of thyroxine

is thus seen to be intracellular, aerobic and enzymatic.

The effect of hypophysectomy on thyroxine synthesis in the organism has also been studied with the use of tracer doses of radio-iodine.²⁰ The incorporation of iodine into the thyroid gland was much slower and in lesser amounts in hypophysectomized animals. The conversion of iodide to di-iodotyrosine was unimpaired, but the formation of thyroxine was greatly diminished or almost inhibited.

The extrathyroidal production of thyroxine or thyroxinelike substances by iodination of proteins in the test tube has directed attention to the possibility of a similar synthesis in the thyroidless organism. Chapman³⁰ found that the level of iodine intake had a significant effect on the weight, surface area, metabolic rate and food utilization of thyroidectomized animals, those with higher iodine ingestion showing an effect that suggested to the author that iodine might play a role in the production of a thyroxinelike substance in the tissues. This aspect of extrathyroidal hormone production was firmly established by Chaikoff and his collaborators³¹ through the use of radio-iodine as an indicator. From two to eight months following thyroidectomy, radio-iodine was injected into young rats, which were then killed at intervals of two to ninety-six hours after the injection. The liver, muscles and small intestines showed measurable quantities of labeled thyroxine and di-iodotyrosine. The completeness of the thyroidectomy was checked both by serial section and by the radio-autographic technic. These experiments indicate that tissues other than the thyroid maintain a primitive ability to elaborate a thyroidlike substance. This is confirmation of the concept of Means³² regarding the priority of the hormone over the gland in the evolutionary scale, the evolution of the gland representing a more efficient method of hormone production.

THE ANTITHYROID GOITROGENS

Compounds that possess antithyroid properties fall into two general categories: those that act without producing goiter, of which iodine and radioactive iodine are examples, and those that cause marked hyperplasia and at the same time depress thyroid function. The latter embrace the cyanides, thiocyanates, sulfonamides and thiourea, with its derivatives. This subject has been extensively reviewed by Williams³³ and by Riker and Wescoe.³⁴

The goitrogenic action of cabbage, demonstrated in 1929 by Chesney, Clawson and Webster,³⁵ was shown by Marne et al.^{36, 37} to be common to the entire genus of Brassica and to be due to contained cyanides. The condition produced was in essence an iodine-deficiency goiter, since it could be prevented by administered iodine and was due to

gland has been claimed to parallel its total iodine rather than its thyroxine iodine content.⁴ Although Harington dismisses the evidence as scanty, if true, it invalidates the hypothesis that thyroxine is in fact the circulating hormone and has directed attention to the parent protein, thyroglobulin, or a peptide derived therefrom.

Sensitive immunologic precipitin tests,⁵ however, have failed to reveal circulating thyroglobulin, which is active orally in the thyroidless animal. If it were the true hormone one would therefore have to assume that after its degradation for absorption by the intestinal tract it was resynthesized in the absence of the thyroid gland. More direct evidence excluding thyroglobulin itself as the circulating hormone has been offered by Bassett, Coons and Salter,⁶ who found the major part of the circulating iodine in the albumin fraction, although the highest concentration of iodine was in the alpha and beta globulins.

Harington² presents immunologic experiments that strongly support his view that thyroxine is the thyroid hormone. He immunized animals with thyroxine-protein complexes, whose antigenic specificity was determined by thyroxine and di-iodotyrosine groups, to produce an antiserum whose antibodies were specifically adapted to combine with the molecule of the physiologically active substance and consequently to interfere with the action of this substance in another animal by a process analogous with passive immunization. The antisera thus developed against the artificial thyroxine proteins did not lower the metabolic rate of normal animals, but they did prevent, almost completely, the characteristic rise in metabolic rate caused by the administration of either thyroglobulin or thyroxine. This neutralization of the effect of thyroxine by the antisera showed that the circulating antibodies, which contained combining sites adapted to thyroxine, interfered with the access of the latter to its normal sites of action in the tissues. This conclusion is supported by earlier work of McClendon and his associates,⁷ who found that the calorogenic action of thyroglobulins from goiters of all types depended on their thyroxine content only and concluded that this content rather than total iodine determined calorogenic effect.

If the circulating hormone is thyroxine or some other hydrolytic product of thyroglobulin, the gland itself should contain an enzyme system capable of breaking down thyroglobulin by proteolysis into smaller components that can pass across cell membranes. The existence of such an enzyme system has been demonstrated and its activities quantitated by DeRobertis and Nowinski,⁸ who found a 100 per cent increase in proteolytic activity in the thyrotoxic gland as compared to the normal, and a 25 per cent decrease in iodized thyrotoxic glands and in nontoxic diffuse goiters.

Meyer and his co-workers,⁹ by injecting thyroglobulin, produced an immune serum that was effective in producing passive immunization against thyroglobulin in normal rabbits as determined by a reduction in the metabolic rate and the prevention of an increase in metabolic rate from injections of the same thyroglobulin used as an antigen.

Thyroxine synthesis had been accomplished in the laboratory by Harington and Barger¹⁰ in 1927. Proof of the steps in the biosynthesis of thyroxine has been furnished by radio-iodine studies. The progression from the iodine-free amino acid tyrosine to the physiologically active tetra-iodo-thyronine or thyroxine by way of di-iodotyrosine, although logical, had not been established biogenetically. The total iodine content of the thyroid gland is accounted for by thyroxine and di-iodotyrosine, both of which have been shown to occur abundantly in the thyroid gland. What accomplishes the coupling of di-iodotyrosine to form thyroxine? Insight into this mechanism was first clearly furnished by Ludwig and von Mutzenbecher,¹¹ who were able to iodinate casein, producing products whose physiologic activity was shown to be due to the formation of thyroxine. This remarkable synthesis has since lent itself to the inexpensive production of iodinated proteins of considerable physiologic potency that have been found useful in animal husbandry in increasing milk yield.^{12,13} Only two mechanisms are available to explain this formation of thyroxine: either the protein contained thyronine (thyroxine less all four of its iodine atoms), which directly added iodine to form thyroxine, or the iodine produced di-iodotyrosine from tyrosine and was then converted into thyroxine. Proof that the latter type of conversion could occur in minimal amounts was first adduced by von Mutzenbecher¹⁴ in 1939 and was shown by Harington and Pitt Rivers¹⁵ to depend on biologic oxidations. The final proof of the ability of thyroid tissue to convert di-iodotyrosine into thyroxine was furnished by tracer studies utilizing radio-iodine. This was accomplished by two methods. In the first, radioactive iodine was injected into animals and the distribution of radioactivity in the body subsequently determined; in the second, the respiration of thyroid-tissue slices was studied in a medium to which radioactive iodine had been added and whose fate could be traced.

Following the injection of radio-iodine into animals, there is rapid concentration of iodine in the thyroid gland.¹⁶⁻¹⁹ This occurs within a matter of minutes and proceeds until as much as 50 per cent of the radioactive material is found in the gland after forty-eight hours. The radioactive iodine is distributed among three fractions—morganic iodide, di-iodotyrosine and thyroxine—with increasing amounts of di-iodotyrosine and thyroxine with the passage of time. In fact, Morton and his co-

and a decrease in the pituitary gland. These investigators⁶⁴ state, "Thiourea and sulfadiazine, by depressing the formation of active thyroid principle, cause an increased release of thyrotrophin from the pituitary into the blood where, however, it appears in reduced amount because of its removal and increased utilization by the enlarging thyroid gland." Although the decreased amount of the thyroid-stimulating hormone found in the pituitary glands of the drug-treated animals is not explained, it has been shown by Albert et al.⁶⁵ that physiologically inactive amounts of these goitrogens augment the action of the thyroid-stimulating hormone when mixed with it *in vitro*. This synergism is also illustrated by the greater hyperplasia of the thyroid gland in animals treated with both thiouracil and thyrotropic hormone as compared with that in animals treated with either alone.

Whereas the goitrogenic action of the cyanides and probably of the cyanates could be inhibited by iodides, this was not found to be true with the thiourea derivatives,⁶⁶ which were in fact iodine-resistant goitrogens. But thyroxine or desiccated thyroid was early shown to prevent and abolish the goitrogenic and antithyroidal effect of these compounds as well as of the sulfonamides,³²⁻³³ indicating that they do not function by inhibiting the action of the thyroid hormone in the blood or peripheral tissues. Moreover, Malkiel⁶⁷ has found no destructive or inactivating effect of thiouracil and sulfaguanidine on endogenous circulating thyroxine.

The effect of the antithyroidal goitrogens on the metabolism of iodine has been explored by conventional techniques and through the use of radioactive isotopes of iodine. Thiouracil and sulfadiazine have been shown to cause nearly complete disappearance of iodine from the thyroid gland in five days.⁶⁸ This effect is inhibited by removal of the hypophysis or administration of thyroxine. Iodine reaccumulates after withdrawal of the drug, but this reaccumulation is retarded by hypophysectomy or the administration of thyroxine. The relation between the dose of thiouracil and thyroid weight and iodine content is quantitative enough to be used for the assay of new compounds.⁶⁸⁻⁶⁹

By studies of thyroid slices with radioactive iodine *in vitro*, Franklin and Chaikoff⁷⁰ found that the sulfonamides inhibited the formation of diiodotyrosine and thyroxine but did not alter the absorption of inorganic iodide from the surrounding medium. Thiouracil and thiocyanate were similarly shown by these investigators⁷¹ to depress or inhibit the formation of thyroxine and diiodotyrosine *in vitro*. They differed in their effect on iodine concentration by thyroid slices, however, thiouracil having little effect and thiocyanate causing marked depression of iodine uptake by the surviving tissues.

The inability of large amounts of iodine to overcome the stasis of hormone production caused

by thiourea was demonstrated in rabbits by Baumann, Metzger and Marine,⁶⁶ who showed that the drug caused rapid decrease in both thyroxine and nonthyroxine iodine in the gland itself, with excretion of the excess iodine in the urine. Further studies *in vivo* with radio-iodine have confirmed the result of the studies *in vitro* — namely, that thiouracil interferes in the living animal with the incorporation of iodine into thyroxine and diiodotyrosine in the thyroid gland⁷² and thus causes cessation of hormone synthesis.

Further details of the mechanism of action of thiouracil on iodine metabolism have been supplied by studies on the chick with radio-iodine. It was first demonstrated that thyrotropic hormone produces thyroid hypertrophy within twenty-four hours,⁷³ but no increased iodine uptake occurred until hyperplasia was marked. This accelerated uptake was not maintained with continued stimulation. In addition, thyrotropic hormone caused early and striking acceleration in the loss of radio-iodine from the gland, so that 75 per cent of the quantity initially stored was lost during the first day. This is interpreted as being due to "accelerated secretion of thyroid hormone from the gland induced by thyrotropic stimulation."

Next, a comparison was made of the effects of thiouracil and of thyrotropic hormone on the collection of radio-iodine and on the histology of the thyroid gland in the chick.⁷⁴⁻⁷⁵ The histologic changes produced were indistinguishable except for a lag of five days in the appearance of alterations caused by thiouracil. Within an hour after the injection of thiouracil, however, maximal inhibition of the uptake of radio-iodine occurred, with a gradual loss of this inhibitory effect over twenty-four hours. Following the withdrawal of thiouracil, the glands of the treated chicks collected radio-iodine in larger quantities than did those of the controls, in amounts similar to those collected by glands made hyperplastic with injections of thyroid-stimulating hormone. The inhibition of iodine collection resulting from thiouracil in the intact thyroid gland contrasts sharply with the *in vitro* studies previously described,⁷¹⁻⁷² but both sets of experiments confirm the hypothesis that thiouracil interferes with hormone synthesis by interfering with the metabolism of iodine. Thiouracil inhibited collection of radio-iodine by normal chick thyroid and by that made hyperplastic through thyroid-stimulating hormone and with thiouracil. Salter, Cortell and McKay⁷⁶ reached similar conclusions concerning the role of thiouracil — that it prevents the conversion of iodide to diiodotyrosine and thyroxine without, however, impeding the synthesis of uniodinated thyroid protein.

A more recent study by Chaikoff and his associates⁷⁷ has confirmed the depressing effect of potassium thiocyanate on the uptake of radio-iodine by thyroid tissue, either *in vitro* or in living animals.

increased thyroid activity caused by depressed oxygen consumption from the cyanide. Depressed oxygen utilization increased thyroid activity, goiter results if iodine is lacking in the face of added demands on the thyroid gland.

That the thiocyanates in addition to the cyanides exert a goitrogenic and antithyroidal effect was first observed by Barker^{38, 39} in hypertensive patients under treatment with potassium thiocyanate. Many similar cases subsequently reported have been reviewed by Estes and Keith⁴⁰. These goiters occur in about 4 per cent of such patients³⁹ and are characterized by thyroid hyperplasia, the signs and symptoms of myxedema, occasionally by exophthalmos and by an increased urinary excretion of inactivated thyrotropic hormone. Rawson and his co-workers^{41, 42} believe that the thiocyanate prevents the synthesis of thyroid hormone at some point distal to the uptake of iodine, since they were able to demonstrate excessive uptake of radioiodine by thiocyanate-induced goiters. Decreased hormone elaboration leads to hypometabolism and to stimulation of the anterior pituitary body, with excessive production of thyrotropic hormone. This causes thyroid hyperplasia without a corresponding increase in hormone output — "a hyperplasia of frustration." The administration of desiccated thyroid prevents or relieves thiocyanate goiter.

Thiocyanate therapy may also cause acute goiter clinically resembling thyroiditis⁴³ and pathologically showing extreme parenchymatous hypertrophy and hyperplasia⁴⁴ but without papillary infolding or lymphocytic infiltration. The colloid stains well, and the irregularity of the acini and a tendency toward invasiveness suggest neoplasia.

The antithyroidal and goitrogenic properties of the cyanides and cyanates were of experimental and toxicologic interest but failed of clinical application. In 1941, however, British and American investigators simultaneously revived interest in the chemotherapeutics of Graves's disease by parallel studies of new antithyroidal goitrogens. Kennedy and his co-workers⁴⁵ found that Brassica-seed diets produced large goiters in rats in spite of simultaneously administered iodide, the goiters required the presence of thyrotropic hormone for development or maintenance, since they did not develop in hypophysectomized animals and regressed after hypophysectomy^{46, 47}. The active goitrogenic principle was demonstrated to be thiourea or allyl thiourea⁴⁸.

Meanwhile, Richter and Clisby,⁴⁹ in searching for an improved rat poison, discovered that phenyl thiourea caused marked hyperplasia of the thyroid gland. Somewhat earlier, the MacKenzies and McCollum⁵⁰ found that sulfaguanidine caused marked thyroid hyperplasia.

In this initial phase of study, chief emphasis had been placed on goitrogenesis — an iteration of the early work with the cyanides and cyanates. Astwood and others⁵¹ and simultaneously the Mac-

Kenzies⁵² directed attention to the more important effect of these compounds as inhibitors of thyroid function. Both groups of investigators first studied the sulfonamides and thiourea, finding the latter many times more effective than the former as an antithyroidal drug. Both caused thyroid hypofunction, with reduced oxygen consumption and impairment in growth and development. The thyroid glands were enlarged, hyperemic and hyperplastic, with decreased colloid and increased acinar-cell height. Papillary infoldings of the epithelium were frequently observed. Omission of the drugs was followed by histologic and physiologic return to normal.

The shifting of emphasis from goitrogenesis to antithyroidal activity was followed by widespread research into the compounds that maximally depressed thyroid function and were only incidentally productive of thyroid enlargement. Thiourea, thiouracil and their derivatives were found to be the most potent compounds for inhibiting thyroid function⁵³. In a more recent study of over two hundred and twenty substances, Astwood, Bissell and Hughes⁵⁴ found two types of chemical structure associated with antithyroidal activity. The more active substances were derivatives of thiouracil and possessed a thiocarbonamide grouping, the less active substances possessed an aminobenzene group, such as the sulfonamides, and were a fourth as active as thiouracil. The most active of the former group proved to be 6-N-propyl thiouracil.

To this "periodic table" of antithyroidal goitrogens established by Astwood, other investigators⁵⁵⁻⁶¹ added and undoubtedly will continue to add various active compounds, since the slightest shift in chemical structure or linkage produces marked pharmacologic differences.

The morphologic and physiologic effects of these compounds, particularly thiouracil, have been abundantly studied so that an accurate postulation of the mechanism of hormone inhibition can be constructed. Thiouracil retards growth, induces cretinism in newborn rats and antagonizes the effects of injection of the growth hormone of the anterior pituitary body^{62, 63}. The presence of the pituitary is essential for the production of goiter with these drugs,^{48, 61, 62} since no thyroid hyperplasia occurs in hypophysectomized animals following their administration, in fact, the thyroid gland regresses as in untreated hypophysectomized animals. The goitrogenic effect results from pituitary stimulation and not from direct action by these compounds on the thyroid parenchyma.

No increase of thyrotropic hormone is demonstrable in the blood or hypophysis of rats treated with thiourea or sulfadiazine, in fact, there is a decrease as compared with marked increases found in thyroidectomized animals⁶⁴. Animals pretreated with thiourea and then thyroidectomized showed an increase of thyrotropic hormone in the blood.

so-called "chemical thyroidectomy" and in the preoperative preparation of patients for thyroidectomy, either alone or in association with iodides

When thiouracil was used as the sole agent in the treatment of Graves's disease, about 50 per cent of patients remained in remission and the other 50 per cent relapsed within two weeks to five months⁸⁴⁻⁸⁶. In general, patients treated for nine to twelve months had a smaller relapse rate than those treated for shorter periods, but Williams⁸⁶ obtained remissions lasting as long as twenty months in several patients who were under treatment for only two months. On the other hand, relapses occurred in several patients who had been treated for as long as twenty months. Lasting remissions occurred more frequently in female patients with small glands and mild hyperthyroidism.

The use of thiouracil in the preparation of the patient for thyroidectomy has been extensively reported⁸⁴⁻⁸⁶ and has established itself as the agent of choice for severe cases of thyrotoxicosis because it almost invariably reduces the metabolism to normal and renders a one-stage thyroidectomy feasible in patients who previously required multiple operations. When thiouracil is used as the sole drug, however, the gland is so vascular and friable that hemostasis is arduous and the gland more difficult to handle. Fortunately, the addition of iodides in the preoperative preparation, either in conjunction with thiouracil or for a period of seven to fourteen days preceding the operation, greatly reduces the vascularity and allows adequate control of bleeding at operation. In our experience the two drugs may be used simultaneously up to operation, since thiouracil and its derivatives do not repress the involuting effect of iodine on the hyperthyroid gland^{85, 89, 97}.

During the early experience with thiouracil in the treatment of toxic goiter, it appeared that preliminary administration of iodide slowed the rate of improvement, and it was believed that this was due to the effect of iodine in causing increased hormone storage. More extensive experience has shown that there is considerable variation in the effect of iodide on subsequent thiouracil therapy in Graves's disease,^{84, 87} and this has been our experience. In rats simultaneous administration of sodium iodide and methyl thiouracil resulted in the typical iodide effect — flattening of the epithelium and colloid accumulation. The same investigator⁸⁸ found greater inhibition of thyroid function when both substances were administered to thyrotoxic patients than with either alone, and concludes that no specific antagonism between the effects of goitrogenic substances and iodine is apparent, iodine and the thyrotropic hormone or the goitrogens must be supposed to have different points of attack, since the two phases can be accelerated co-ordinately. Danowski, Man and Winkler⁸⁹ also found that previously administered iodine did not significantly interfere with the subsequent antithyroidal effect of thiourea.

The inter-relation between thiouracil and iodine as they affect the hyperplastic gland in Graves's disease has led to a reformulation of the mode of action of iodine in this disease by the Thyroid Clinic of the Massachusetts General Hospital¹⁰⁰. The function of iodine in supplying an essential ingredient for thyroid economy is termed its "iodinating action," which may be served by as little as 0.075 mg of iodine daily. In Graves's disease the rapid manufacture of thyroid hormone creates an iodine uptake by the gland two or three times that in normal persons. The administration of iodine in daily doses of 60 mg or more meets the demands of increased hormone production and thus induces regression of the gland toward normal — the so-called "involuting action" of iodine. Under thiouracil treatment the hyperplastic gland in Graves's disease becomes more hyperplastic. In spite of the fact that thiouracil prevents the utilization of iodine for hormone synthesis, the iodine causes involution of the thyroid gland in Graves's disease. Therefore, it is concluded that iodine exerts an iodinating and an involuting action on the gland in Graves's disease and that these two actions can be separated by means of thiouracil.

Toxic Reactions

Early observations quickly showed the varied toxicity of thiourea and thiouracil. The principal toxic reactions comprised the following dermatitis, drug fever, swelling of the submaxillary glands, leukopenia and agranulocytosis. Less frequent reactions are the following: edema of the legs, purpura, hematuria, Mikulicz's syndrome, pericarditis, periarteritis nodosa and psychosis. These reactions have been described and reviewed extensively¹⁰¹⁻¹⁰³. In addition, they have been the subject of co-operative studies covering 1091 patients in one group¹⁰⁹ and 5745 in another¹¹⁰. It is clear from these analyses of the toxic manifestations in large groups of cases that approximately 15 per cent of all patients will show some type of adverse reaction to thiouracil. All the principal reactions promptly disappear on omission of the drug except agranulocytosis, which is the most serious complication of thiourea and thiouracil therapy and requires special consideration because of its frequently fatal issue. It occurs in about 2.5 per cent of cases, with a varying fatality rate of 15 to 25 per cent and an overall mortality in large series that is constant at 0.4 to 0.5 per cent. Agranulocytosis tends to occur in the early weeks of treatment, but no general rule can be laid down that will guarantee freedom from serious hematologic reactions. As Lesses and Gargill¹⁰⁶ state

Dosage, duration of treatment, constant or intermittent therapy, associated clinical phenomena and premonitory symptoms have not proved safe guides. Serious reactions have occurred at both high and low dosage levels, with short and with long treatment and with both constant and intermittent administration of the drug.

maintained on an iodine-poor diet. Following the disappearance of potassium thiocyanate from the circulation, the whole gland does have an increased uptake of radio-iodine, but this increase is not apparent when expressed in terms of unit weight of tissue. Thus, the drug does interfere with the removal of iodine from the circulation when iodine is not readily available in the diet. It also inhibits conversion of inorganic iodide to di-iodotyrosine and thyroxine, as shown by low thyroxine content of the gland and decreased levels of protein-bound iodine in the blood. VanderLaan and Bissell⁷⁸ have likewise confirmed this course of events by showing that rats fed propyl thiouracil readily take up radio-iodine in their thyroid glands but retain it only for a short time, possibly because it is not hormone-bound, and that in the presence of both propyl thiouracil and potassium thiocyanate there is delayed and only moderate iodine uptake by the gland. They conclude that "in the presence of thiocyanate the ability of the thyroid gland depleted of iodine to take up injected iodine is considerably impaired." These recent studies indicate the importance of time relations in the study of the influence of goitrogens on iodine uptake.

The evidence that the biosynthesis of thyroxine is intracellular, aerobic and enzymatic has been discussed above. The iodination of tyrosine to di-iodotyrosine requires liberation of iodine from iodide. The formation of di-iodotyrosine and thyroxine is "linked with aerobic oxidations involving the cytochrome-cytochrome oxidase system."⁷⁴ The effect of the sulfonamides and thiouracil on this enzyme system is controversial, Franklin and Chaikoff⁷⁰ observing no effect with the sulfonamides and Dempsey⁷⁵ noting that thiouracil readily inhibited the peroxidase reaction in thyroid tissue but did not affect the cytochrome oxidase reaction. McShan, Meyer and Johansson⁷⁹ found no inhibition of cytochrome oxidase or of succinoxidase in thyroid tissue by sulfonamides and thiouracil. On the other hand, Paschkis and his co-workers⁸⁰ report that thiouracil and the sulfonamides inhibit the cytochrome oxidase *in vitro* as well as in the thyroid gland itself. Bevelander,⁸¹ after studies on sea-urchin egg development, concluded that thiourea acts by inhibition of enzyme systems necessary for the growth of the sea urchin. Tipton and Nixon⁸² observed significant depression of succinoxidase and cytochrome oxidase in the liver of rats.

Thiouracil acts by preventing iodination and hormone synthesis, but it is still not clear whether it acts as an antioxidant, through depression of the enzyme systems or by some mechanism other than that of inhibition of oxidation.

THIOURACIL AND RELATED COMPOUNDS

Clinical Use

Since Astwood⁸³ first used thiourea and thiouracil in the treatment of hyperthyroidism, numerous re-

ports have appeared dealing with many thousand of cases. The experience with thiouracil is extensive, but its toxicity has led to clinical studies with other derivatives and related compounds. Excellent reviews concerning large series of cases treated with thiouracil for long periods have been published by Astwood,⁸⁴ Barr and Shorr⁸⁵ and Williams.⁸⁶

The anatomic effects produced in the human thyroid gland by thiouracil have been chiefly studied in the hyperplastic gland of Graves's disease. The size of the gland may increase, decrease or remain unaltered, but the gross increases in human beings have not been so striking or so constant as those in experimental animals. Prolonged treatment has usually resulted in a decrease of the gland⁸⁷ unless myxedema supervenes. Histologically, however, there is great similarity to the experimental effect with increased thyroid hyperplasia, loss of colloid and increased vascularity.^{88, 89} Changes in the pituitary gland similar to those found in animals—increased basophilism and absent eosinophilism—have been reported.⁹⁰

Physiologically, thiouracil decreases the basal metabolic rate, frequently at the same rate as iodine,^{84, 88} and in many cases causes clinical myxedema if continued for several months.^{84, 85} Myxedema, however, has not yet been conclusively produced by thiouracil in persons with normal thyroid function,⁸⁴ the normal economy evidently possessing adequate homeostatic mechanisms for resisting the usual goitrogenic and thyroid-depressing effects of this compound. Following the administration of thiouracil in Graves's disease, the uptake of tracer doses of radio-iodine is greatly diminished with an increased urinary excretion,⁸⁸ as previously described in animal studies. The hormonal iodine of the blood returns to normal,⁹¹ the blood cholesterol rises,⁹² the calcium, phosphorus and protein balances become more positive and creatinuria decreases.⁹³ In general the physiologic effects produced are such as would occur with amelioration of thyrotoxicosis and a return to the euthyroid state. These changes, which occur far more regularly than with iodine therapy, may take from several weeks to several months for completion.

The effective dosage of thiouracil for initial therapy is generally 0.6 gm daily, in doses of 0.1 gm at regularly spaced intervals. The dosage is reduced as the basal metabolic rate approaches normal, and maintenance doses of 0.05 to 0.2 gm are utilized for long periods. Intermittency of treatment is avoided, since it is considered to be a contributing factor in toxic reactions. Subjective and objective clinical improvement usually appears within seven to ten days after the initiation of therapy. The basal metabolic rate and blood-cholesterol levels serve as adequate laboratory guides in the regulation of dosage.

Thiouracil has been used in two ways as the sole agent in the control of thyrotoxicosis to produce a

Recent progress reports by Hertz and Roberts¹²³ and by Chapman and Evans¹²⁴ deal with the use of radioactive iodine in a total of 51 cases followed up to five years, the former continuing to advocate supplementary iodide therapy following the ingestion of radio-iodine but the latter finding it unnecessary.

Radioactive iodine is prepared in a cyclotron by nuclear bombardment of metallic tellurium that becomes transmuted into iodine. This must be dissolved, distilled and reduced to sodium iodide. The final product as administered is dissolved in distilled water to contain 14 to 79 mc of twelve-hour iodine. This is ingested by the patient within one to four hours after conclusion of the bombardment. The dosage given is dependent on the estimated weight of the thyroid gland, about 0.5 to 1 mc of twelve-hour iodine per gram of thyroid being utilized, in doses ranging from 5 to 25 mc in one series¹²³ and an average of 40 to 50 mc in the other.¹²⁴ Large doses may cause radiation sickness. Ordinary iodine therapy should be withheld for several weeks before the administration of radio-iodine, to ensure adequate concentration of the radio-iodine by the thyroid gland. Biopsies indicate that radio-iodine causes fibrosis of the gland similar to that seen with external irradiation. Adequate doses, either single or multiple, have caused sustained remissions in about 80 per cent of the patients treated. Personal observations in a small number of cases indicate that single doses ranging from 8 to 25 mc were frequently ineffective in producing a remission and required supplemental use of iodides.

More data must be accumulated before final judgment can be made of the place of radio-iodine in the therapy of Graves's disease, particularly regarding the undesirable late effects from the "internal radiation." On a theoretical basis the administration of radioactive iodine seems unlikely to produce deleterious late effects. The beta rays emitted have a maximum range of a few millimeters of tissue, and whatever radio-iodine is not absorbed by the thyroid gland is excreted in the urine.

BLOOD-IODINE STUDIES

Determination of the blood-iodine level has become increasingly important in the diagnosis and management of thyroid disease. The concentration of precipitable or protein-bound iodine in the serum is probably an index of the amount of circulating thyroid hormone and hence is also called "hormonal iodine." The methods, which are relatively exact but arduous, require considerable skill in the techniques of analytical chemistry, so that they are not suitable for routine clinical laboratories. The information obtained, however, is sufficiently valuable to warrant greater clinical use.

Curtis^{125, 126} has recently reviewed a large experience extending over thirteen years utilizing whole-blood-iodine levels rather than those of precipitable serum iodine. In toxic goiter, whether diffuse or nodular, the level of blood iodine was consistently elevated to about twice normal (4 microgm per 100 cc as contrasted with 8 microgm per 100 cc). In his final conclusion, however, he states "The determination of the basal metabolic rate is a more reliable test of thyroid activity than the level of the unfractionated whole blood iodine. However, both determinations, considered together, are superior to either alone."

Winkler and his collaborators have contributed important studies on the precipitable serum iodine in hypothyroidism¹²⁷ and hyperthyroidism¹²⁸ and on the effect of ingested desiccated thyroid in subjects with normal thyroid function.¹²⁹ In untreated myxedema the serum iodine was characteristically subnormal or absent, treatment with thyroid caused a linear elevation in the level of serum iodine in accordance with the dosage of thyroid, 0.07 gm (1 gr) elevating the serum iodine by 2 microgm per 100 cc. The basal metabolic rate responded more slowly than the iodine levels to alteration in the thyroid state.

In hyperthyroidism at least 95 per cent of all cases had elevation of the precipitable serum iodine. This elevation frequently declined with administration of iodides — occasionally to normal levels — and was restored to normal or subnormal levels following radical subtotal thyroidectomy. Low values frequently persisted permanently, associated with normal metabolic rates but with slight elevations in the serum cholesterol and some clinical evidence of mild hypothyroidism. The level of the serum iodine, therefore, appeared to be more sensitive than the basal metabolic rate in measuring thyroid hypofunction.

When desiccated thyroid was administered to normal subjects there was far less change in the metabolic rate and serum iodine than in myxedema. The administration of 0.7 to 2.0 gm (10 to 30 gr) of dried thyroid, however, caused abnormally high serum iodine, an elevated basal metabolic rate and clinical signs of thyrotoxicosis. Although the normal subject was resistant to thyroid, once enough was given to raise the serum iodine, the correlation between rises in that value and the basal metabolic rate was exactly the same as that in myxedematous patients. Two conclusions were drawn from this study: normal tissues are as sensitive to thyroid as myxedematous and the degradation of normal iodine to inorganic iodine by the normal thyroid gland probably explains the tolerance of euthyroid subjects to large doses of thyroid. This paper contains several instructive graphs showing the parallelism between precipitable serum iodine and basal metabolic rate when thyroid is administered.

Because no protective treatment is available, frequent observation of the patient receiving thiouracil is essential, and white-cell counts should be done three times a week, with estimation of the neutrophil percentage whenever the total white-cell count is below 5000. The patient should be cautioned to report promptly the development of fever, dermatitis or sore throat. If severe neutropenia or agranulocytosis develops, the drug should be promptly omitted and vigorous therapy with penicillin and transfusions should be started.

The unpredictable occurrence of agranulocytosis with thiouracil therapy must be balanced against the risks of thyroidectomy. Since many of these risks are caused by the inability of iodine to induce an optimal remission, the use of thiouracil offers an opportunity to avoid the mortality associated with surgery in severely toxic cases. Although the risks of thyroidectomy are greatest in patients with severe thyrotoxicosis or with associated cardiovascular disease, a fatal reaction to thiouracil may occur in mild or uncomplicated cases. For this reason, thiouracil is best employed as a preoperative agent along with iodine in patients who are severely toxic. The mildly toxic group is best managed with iodine followed by thiouracil and thyroidectomy if iodine alone fails to induce and maintain a complete remission. Thiouracil also has a proper place in the treatment of patients who refuse operation or who are unable to have surgery because of coincidental serious disease or when adequate surgical facilities are not available. Patients with toxic nodular goiters and a small group with exceptionally large diffuse toxic goiters should be subjected to thyroidectomy after preparation with either iodine alone or with thiouracil and iodine, depending on the degree of toxicity. Thyroidectomy is eventually indicated in this group, either because of pressure effects or because of possible neoplastic disease in the nodular goiters.

Continuous therapy with thiouracil, if essayed, should be restricted to patients who can be closely observed and whose temperament and occupation readily lend themselves to such observation. Another hazard of continuous thiouracil therapy is the possibility that it will stimulate carcinogenesis in the thyroid gland. Thiourea, when administered to rats together with the carcinogen acetaminofluorene, produces rapidly growing tumors, which neither alone evokes.¹¹¹ Paschkis and his associates¹¹² found that thiouracil induces mitosis stimulation in rats kept at low temperatures, as measured by the colchicine technic.

The toxic manifestations of thiouracil have led to clinical trials of many related compounds in an effort to circumvent the undesirable side effects. Thiobarbital,¹¹³⁻¹¹⁵ methyl thiouracil,¹¹⁶⁻¹¹⁹ amino thiazole,¹²⁰ 6-N-propyl thiouracil^{121, 122} and many others have been utilized.^{97, 123} The first three proved at least as toxic as thiouracil. Amino thia-

zole is still under study. Propyl thiouracil in preliminary clinical studies produced only urticaria dermatitis but was highly toxic to rats,¹²⁴ so that no final estimation of its toxic potentialities can be made at present. Sensitization phenomena appear to be frequently linked with the toxic qualities of all these compounds.¹⁰¹⁻¹⁰⁵

OTHER ANTITHYROIDAL AGENTS

The effectiveness of the antithyroidal goitrogen depends on their interference with the production of thyroid hormone. They do not in themselves antagonize or neutralize the effect of circulating thyroxine so that they are antithyroidal by indirect rather than specifically. Recently, certain compounds have been claimed to be particularly antagonistic to thyroxine itself. Carter and his collaborators¹²⁵ found a substance in ox and whale liver and in human urine—identified as paraxanthine (1, 7-dimethylxanthine)—that was capable of converting the temperature-heart-rate curve of the summer frogs' heart into the curve of the winter frogs' heart. This substance, which was isolated in crystalline form, appeared to counteract the effect of thyroxine in rats. Barker¹²⁶ and Williams,¹²⁷ however, were unable to find significant antithyroidal action from this drug as measured by effects either on oxygen consumption or on tadpole metamorphosis. It had no observable result when given to a thyrotoxic patient for a period of eleven days.

Mansfeld¹²⁸ extracted from the thyroid gland and human serums crystalline substances called "thyrothyryl A and B" that are capable of producing as much as a 50 per cent lowering of oxygen consumption in rats. This work has not yet been confirmed but the compounds involved may be related to certain structural analogues antagonistic to thyroxine investigated by Woolley.¹²⁹ These were newly synthesized ethers of N-acetyl di-iodotyrosine that did counteract the pharmacologic effects of thyroxine on tadpoles but that, in the absence of thyroxine, were chemically close enough to it to have a slight thyroxinelike effect themselves. This development may hold promise for eventual isolation of a natural antithyroidal compound without the toxic complications of the thiourea derivatives.

RADIOACTIVE IODINE

In 1938 Hertz, Roberts and Evans¹⁶ introduced radioactive iodine as an aid in the study of thyroid physiology. The hyperthyroid gland was found to absorb as much as 80 per cent of small tracer doses of radio-iodine.¹³⁰ Its application to the treatment of Graves's disease by Hertz and Roberts¹³¹ and by Hamilton and Lawrence¹³² quickly followed. The latter authors reported 3 cases of hyperthyroidism that were completely remitted after adequate doses of radio-iodine. In the former series ordinary iodides were given in addition to the radio-iodine.

EXOPHTHALMOS IN THYROID DISEASE

The problem of exophthalmos associated with toxic goiter has continued to excite the interest of investigators and to harass and mystify the clinician. Two exhaustive reviews, dealing particularly with the clinical problems, have recently appeared by Mulvany¹⁴⁰ and Woods,¹⁴¹ whereas the experimental aspects have been most instructively studied by Albert.¹⁴² Woods summarized the present status of the subject as follows:

A critical review of all the various theories and experiments in the etiology of the exophthalmos of primary toxic goiter permits but one conclusion—the problem is still unsolved. The evidence indicates that exophthalmos is probably not related to a thyrotoxicosis and not related at all to a sympathicotonia. The weight of evidence would indicate that both the thyrotoxicosis and the exophthalmos are related in some way to the action of an anterior pituitary hormone or several hormones. Any effect by thyroxine appears to influence favorably the exophthalmos. Deficiency in the gonads or adrenal cortex may play a considerable role in the picture.

If the exophthalmos is in truth initiated by an anterior pituitary hormone, the means by which it accomplished this end is still a mystery. The anatomical evidence all points strongly to the impossibility of the eye being pushed or pulled forward by any muscular action. Edema and hypertrophy of the orbital contents with some inflammatory reaction is present but whether this is primary or secondary is undetermined. Once initiated, however, the orbital hyperplasia may continue or persist despite the control of the metabolic phases of the disease.

There is considerable clinical evidence that any measure that quickly and completely alleviates the thyrotoxicosis may worsen the hyperophthalmia of patients with severe or malignant exophthalmos.¹⁴³⁻¹⁴⁶ Although this is not invariable, its occurrence is frequent enough so that in thyrotoxic patients with severe ophthalmopathy the effect of any therapy on the eyes should be given first consideration. Ordinarily this would call for gradual control of the thyrotoxicosis, such as with external irradiation, chemical thyroidectomy with thiouracil or iodide or radioactive iodine therapy.¹⁴⁷ A remission induced with radioactive iodine in 1 case did not increase severe exophthalmos.¹³⁴ Thyroid administration is perhaps helpful and should be utilized to the point of tolerance for long periods as soon as the intrinsic thyrotoxicosis is brought under control. The work of Winkler¹³⁷⁻¹³⁹ suggests the desirability of administering enough thyroid to raise the serum iodine to thyrotoxic levels. The determination of the basal metabolic rate can be used as an indirect guide to the level of hormonal iodine if facilities for the latter estimation are not available.

Experimentally Albert¹⁴² has conclusively demonstrated that the anterior pituitary gland contains an exophthalmogenic factor that produces striking exophthalmos in the fundulus—the common Atlantic minnow. This factor parallels the thyroid-stimulating hormone of the pituitary gland both qualitatively and quantitatively and may be that

hormone or one closely related. In the fundulus the exophthalmos is due to secretion of fluid by the orbital tissues into the retrobulbar space. The fluid presses the eyeball forward and thrusts it out of the orbit by overcoming the pull of the extraocular muscles. Albert's work holds definite promise for the future elucidation of the clinical problem of exophthalmos.

slightly movable and did not seem to be attached to the cervix. The fundus was not palpable. The mass was also felt on rectal examination.

The temperature was 101°F, the pulse 96, and the respirations 22. The blood pressure was 120 systolic, 80 diastolic.

Examination of the blood showed a white-cell count of 8600, which rose to 10,800 on the fourth hospital day. The urine and stools were normal. X-ray examination revealed a questionable soft-tissue mass represented by an 11-cm. area of decreased density in the pelvis. The cervical discharge was negative for streptococci and gonococci but abundant beta-hemolytic streptococci were cultured from the urine.

In the hospital the temperature remained between 99 and 100°F. On the fourth day the fundus of the uterus was felt anteriorly to the left of the midline, and an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. CARROLL MILLER. We have here the record of a young woman — apparently in good health, without previous disease or surgery — who was seized with a sudden abdominal pain whose nature makes one think that it was dependent on an acute abdominal condition. The disease must have been in the lower abdomen, and we should consider three systems in formulating a differential diagnosis. The urinary tract can be dismissed quickly because of the lack of urinary symptoms. It is true that the patient had urinary frequency, but she had no dysuria in the hospital. Beta-hemolytic streptococci were cultured from the urine. It has been found not infrequently that pathologic conditions in the kidney, the ureter and the bladder may produce a picture simulating an acute abdominal emergency. Pyelitis or ureteral stone will cause pain, spasm, nausea and vomiting, an urge to urinate at frequent intervals and sometimes dysuria. The symptoms that this patient presented, however, do not suggest to me either pyelitis or stone, and the microscopic examination of the urine seemed to rule these out after admission.

The gastrointestinal tract, particularly the small and large bowel, should next be considered. In any acute abdominal condition one first suspects appendicitis. Symptoms of appendicitis are unusual on the left side of the abdomen. There may be a malrotation of the colon, with the cecum and appendix on the left of the midline, some information may be obtained from the x-ray film about the position of the colon, even though a barium enema was not done. The progress of the symptoms suggests a sudden rupture or extension of a long-standing process in the lower abdomen that was not, however, sufficiently virulent to cause peritonitis. In cases of ruptured appendix or a ruptured Meckel's diverticulum, one finds evidence of persistent and

usually widespread peritoneal infection and inflammation. We should always think of sigmoidal diverticulitis in cases of sudden left-sided lower abdominal pain, but it is rare to have diverticulitis in a person in the early decades of life — this patient was thirty years old, and the usual symptoms occur after forty. It is quite possible that a rupture of an infected diverticulum caused a peritoneal reaction at first, which became walled off, with the formation of an abscess. Again, I think that we can rule out rupture of a carcinoma of the sigmoid or rectum because this patient apparently had had no previous bowel disturbance. Examination of the stools was negative for blood, I assume, and she did not present a history of carcinoma, either from obstruction or from other interference with bowel habits. A volvulus of the sigmoid is something that we see fairly often. This may produce rather low-grade obstruction, which becomes more marked as time goes on. It may cause marked peritoneal irritation as the circulation in the twisted loop becomes impaired. It is unlikely, however, that this patient would have recovered from the condition so easily and so well as she apparently did. The confusing finding that turned up later in the illness is the mass in the right side of the pelvis, when the original pain was experienced on the left.

So far as the internal female genitalia are concerned, I think that we must consider first and always the possibility of extrauterine pregnancy. We cannot always depend on the menstrual history in cases of pregnancy because we have all seen patients two, three or four months' pregnant who have had some flow at the usual menstrual time. We assume that this last period, twelve days before the pain started, was a normal one. The patient was obviously an obese woman, and examination of the abdomen was undoubtedly difficult. She may have had pelvic inflammatory disease, with hydrosalpinx, or diffuse ovarian pseudomucinous cysts. She may have had a simple ovarian cyst that was not large enough to cause symptoms of pressure or pain prior to the onset of the present illness. This may have become twisted during the night before she was awakened with pain, and with increasing infarction it may have ruptured. I should like to believe that this process was primarily a rupture of a small hollow viscus or cyst, with flooding of the peritoneal cavity and with gradual subsidence of the diffuse peritoneal reaction and residual fluid into an abscessed mass. Let us not call it an abscess but encapsulated fluid. I should be interested to know what the hemoglobin determination was when she was examined in the hospital.

DR. TRACY B. MALLORY. The hemoglobin determination is not recorded.

DR. MILLER. I think that we should all like to know what the hemoglobin was, because if there was blood in the abdomen there should have been a fairly moderate reduction in the hemoglobin.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., Editor

BENJAMIN CASTLEMAN, M.D., Associate Editor

EDITH E. PARRIS, Assistant Editor

CASE 32461

PRESENTATION OF CASE

A thirty-one-year-old housewife entered the hospital because of lower abdominal pain.

At 5:00 a.m., eight days before admission, the patient was awakened by a sharp pain in the left lower quadrant, flank and thigh. It was intermittent and severe enough to make her cry out. She desired to move her bowels, but could not. The pain persisted all day, without anorexia, nausea or vomiting. Two enemas were administered. Since only a small portion of the fluid was evacuated, the patient swallowed three tablespoonfuls of milk of magnesia. On the following day the pain spread over the entire abdomen and was constant. A physician prescribed "white pills," fluids and bed rest because of

fever. Six days before admission a soapsuds enema initiated a diarrhea that lasted four days. The stools were loose and yellow. The patient felt more feverish, and the abdomen appeared distended. The pain was persistent, but less severe. On the following day she began to have severe cramps over the entire abdomen. Anorexia was marked. The patient lasted until two days before admission, when the patient began a soft diet, the diarrhea eased, and the pain was less severe. On the day before admission the physician advised hospitalization because of continued fever. By the time of admission the pain was reduced to a dull ache in the left flank and over the symphysis. During this illness there was some urinary frequency but no dysuria.

The patient had had three children, the last one a year before entry. The menses had been normal. The last period had begun twelve days before admission and had lasted three days. Four years before admission she had had a post-partum phlebitis for which bilateral ligations were performed. For several years varicose veins had caused some pain on standing, and several had been injected.

On physical examination the patient did not appear ill. She weighed 240 pounds. There was diffuse tenderness throughout the lower abdomen without spasm or rebound tenderness. There was a slight white discharge from the cervix. Motion of the cervix did not cause pain. There was slight tenderness in both vaults, and a large, firm mass was palpated in the right vault that was

ventricle was enlarged, and there were areas of focal collapse in both lower lung fields. An electrocardiogram showed a PR interval of 0.21, with a rate of 100. There was moderate left-axis deviation. A second electrocardiogram six days later was normal. The sedimentation rate at intervals of fifteen minutes was 6, 30, 43 and 46 mm. The blood Hinton reaction was negative.

The temperature rose to 100 to 100.5°F daily. After seven days the patient's condition was unchanged, and she was discharged.

Final admission (eleven days later). After discharge the symptoms were approximately the same as previously until the night before admission, when the patient suddenly experienced a smothering sensation and had difficulty in breathing. This was followed by much coughing productive of white phlegm.

On physical examination there was moderate respiratory distress, with many coarse crackling rales all over the lung fields. The neck veins were engorged, and the liver was palpable. The coughing was accentuated by motion. The heart rate was 130. The respirations were 30. The blood pressure was 132 systolic, 90 diastolic.

Five minutes later the severe dyspnea had disappeared, and the rales were remarkably reduced. During the next twenty-four hours there were two attacks of dyspnea with venous engorgement and rales. Treatment included a total of 24 mg. of morphine, aminophyllin, oxygen and tourniquets. At the end of twenty-four hours the respirations were 9 per minute, the blood pressure was 90 systolic, 62 diastolic. There were a few basal rales bilaterally. The patient died shortly afterward.

DIFFERENTIAL DIAGNOSIS

DR. CONGER WILLIAMS. I think that it would be well to rearrange the symptoms in the order of their appearance and try to decide what this woman had at the time of admission. First of all, for twenty years she had had an insidiously developing productive cough that was worse during the afternoon. Whether that was related to the terminal episodes, I cannot say, it may have been chronic bronchitis, even of slight degree, or chronic irritation from pressure on a bronchus, although I think that that is less likely. Seven years before admission the patient became dyspneic and gained weight. X-ray studies showed an enlargement of the heart. We might consider some sort of underlying heart disease at that time, but the etiology is not clear in the absence of a history of hypertension or findings suggesting significant valvular disease. It might be that the heart had been enlarged from some underlying chronic heart disease but that the patient at the same time had dyspnea from another cause. Dyspnea from heart disease that clears up for seven years on digitalis alone is rather unusual. It is

also possible that she had mild heart disease to begin with, exaggerated by some other complication such as infection or auricular fibrillation, although it is impossible to say which at this point. For five years before admission she had a dull ache throughout the chest, which apparently was constant and was not related to breathing. Constant chest pain, which is unusual and often implies some pressure phenomenon, is a fairly frequent symptom of expanding aortic aneurysm, but is almost unheard of as a symptom of coronary disease over such a long period. Other possible causes of chest pain, constantly present for five years, are few. It is unlikely that an expanding tumor in the mediastinum produced pain in the chest for so long.

Two other symptoms might be considered together. It is stated that the patient stopped giving long lectures because they made her hoarse, I suppose that she was hoarse at other times also. Four years before admission she raised blood-streaked sputum, and it is possible that these two symptoms were related. She may have had a local lesion in the larynx that produced bloody sputum and hoarseness, but I think that that is unlikely. A local malignant tumor of the vocal cords should not persist that long without further complications. Tuberculosis of the larynx might produce blood spitting and hoarseness but is usually associated with widespread pulmonary tuberculosis. I think it likelier that these two symptoms were caused by something lying outside the larynx, probably something in the mediastinum, which not only produced hoarseness by recurrent laryngeal-nerve paralysis but also bleeding by pressure on the bronchial tree.

Another symptom accompanying the constant pain in the chest was described as exertional dyspnea. Whether that was cardiac in origin or related to extrinsic pressure on the bronchial tree, I cannot say at this point.

The next development of importance occurred the day before hospital admission, when after walking half a block the patient felt as if the chest were being squeezed. She also felt as if something were expanding in the chest, which may indeed have been the case. At the same time she was dyspneic and weak and had difficulty in talking. The pain of coronary insufficiency, whether from angina pectoris or from acute thrombosis, is often described as a squeezing or an expanding pain. It is quite possible that this pain that occurred on the day before admission was on a coronary basis. We are not told how long it lasted. Is it known whether it was a matter of a few minutes or hours?

DR. EDWARD BLAND. The pain lasted all day, from 9.30 in the morning. In the afternoon, when Dr. Davenport saw the patient, she was still having pain, but it was less severe.

DR. WILLIAMS. I think that a blood-pressure difference of 20 points systolic between the two arms

It is quite possible that an extrauterine pregnancy did rupture. The peritoneal irritation was caused by either blood or cystic fluid and accounted for the nausea, the distention, the fever and the urge to move the bowels at first and the diarrhea later. Of course, the magnesia would have influenced the bowel habits. At any rate, there seems to have been some resolution of the process as time went on, so that the mass finally became definitely palpable and the fundus of the uterus could easily be outlined and was found to be pushed over to the left side. There was no question at that time of the location of the mass.

May we see the x-ray films that show the area of decreased density?

DR. MILFORD D. SCHULZ: This film shows the area of density in the pelvis. We should pay particular attention to that. The observer used the term "decreased" density. If that is true, it might be a cyst containing fatty material.

DR. MILLER: It is not delineated enough to call it a loop of bowel with air in it?

DR. SCHULZ: There is no indication that it is a dilated loop of small bowel.

DR. MILLER: I do not get much help from the x-ray film. I should guess that this patient had a ruptured ovarian cyst, with persistent bleeding and subsequent formation of a residual mass. My second choice is a ruptured tubal or extrauterine pregnancy.

CLINICAL DIAGNOSIS

Ovarian cyst
Pelvic abscess?

DR. MILLER'S DIAGNOSIS

Ruptured ovarian cyst, with hemoperitoneum and hematoma of adnexa

ANATOMICAL DIAGNOSIS

Dermoid cyst of left ovary, with twisted pedicle.

PATHOLOGICAL DISCUSSION

DR. MALLORY: When the abdomen was opened a moderate amount of orange-colored fluid was seen free in the peritoneal cavity. As exploration was continued a large mass was found adherent to the posterior surface of the uterus impacted in the posterior cul-de-sac. The surgeon's first impression was that it represented endometrial implantation, but on further exploration he found that it consisted of a discrete cyst of the left ovary with a twisted pedicle. It was possible to free it and to remove it without difficulty. When the cyst was opened it was found to contain cheesy material and hair, in other words, it was a dermoid cyst of the ovary, with a twisted pedicle.

DR. MILLER: Had it ruptured?

DR. MALLORY: No.

CASE 32462

PRESENTATION OF CASE

First admission. A seventy-four-year-old woman, a lecturer, entered the hospital because of substernal pain.

For twenty years the patient had had an insidiously developing productive cough that was worse during the winter and when she caught cold. The amount of thick, white sputum gradually increased to an estimated two cupfuls daily at the time of entry. Four years before admission she raised blood-streaked sputum for three days. For several years she had stopped giving long lectures because they made her hoarse. Seven years before admission the patient became dyspneic and gained weight. X-ray examination showed a large heart. With digitalis the symptoms gradually cleared until five years before admission, when a dull ache developed throughout the chest. It was accompanied by exertional dyspnea, anorexia and a loss of 10 pounds in weight. Thereafter the ache was almost constant and was not affected by deep breathing but was made worse by exercise. During these five years there was little change except for increasing fatigability. The day before admission, after walking half a block, the patient felt as if the chest were being squeezed. She walked a little farther and had to call a taxi. The sensation was described as if "something were expanding in the chest" causing pressure and pain that were mostly substernal but radiated all through the chest. She was dyspneic and weak and had difficulty in talking.

The patient had married at the age of nineteen and had one child, who was in good health.

On examination the patient was in no apparent distress except for a cough productive of sticky white sputum every three or four minutes. There were bilateral cataracts obscuring the fundus, although the patient could read. The left heart border extended 10 cm from the midsternal line in the sixth interspace. The sounds were good. Inconstant, coarse rhonchi, which disappeared on coughing, were heard throughout the chest. The diaphragm was low, and the excursions were poor.

The temperature was 99°F, the pulse 90, and the respirations 20. The blood pressure was 150 systolic, 90 diastolic, in the left arm, and 130 systolic, 100 diastolic, in the right arm.

Examination of the blood showed a hemoglobin of 12.6 gm per 100 cc and a white-cell count of 9400. The urine gave a ++ reaction for albumin, and the sediment contained 35 white cells per high-power field. An x-ray film showed marked dilatation of the ascending arch and proximal descending portions of the aorta. The true diameter appeared to measure about 6 cm. The aorta was tortuous and contained calcifications. The trachea was compressed and displaced toward the right. The pulsations of the aorta were not wide. The left

a final cause of death to explain the dyspnea. With paroxysmal attacks one might also consider the possibility of pulmonary embolism, but certainly only as a final complicating episode.

First of all, I should say that this woman undoubtedly had an aortic aneurysm. In spite of her age and the negative serologic findings, it was probably syphilitic. I am almost forced to discard a dissecting aneurysm, in spite of the x-ray picture, because I believe that on the evidence presented it is less likely than syphilitic aneurysm. I think it quite likely that the terminal event was the result of myocardial infarction and congestive heart failure.

DR. TRACY B. MALLORY. Does anyone wish to support the possibility of dissecting aneurysm?

DR. BLAND. I should like to add that this patient presented a problem from the psychologic point of view. Quite properly, the question was raised why she went home so soon. Her physicians did not have much choice in the matter.

CLINICAL DIAGNOSES

Aortic aneurysm, arteriosclerotic type
Coronary occlusion

DR. WILLIAMS'S DIAGNOSES

Syphilitic aortitis, with saccular aneurysm of thoracic aorta and rupture.
Myocardial infarction and congestive heart failure?

ANATOMICAL DIAGNOSES

Syphilitic aortitis, with multiple fusiform and saccular aneurysms of thoracic aorta
Rupture of aorta, with pseudodissection
Media necrosis cystica of aorta
Compression, left main bronchus
Bronchiectasis, left lower lobe
Atelectasis, left lower lobe

PATHOLOGICAL DISCUSSION

DR. MALLORY. The significant pathologic lesion was in the aorta. There was a large fusiform aneurysm involving the entire thoracic aorta and, in addition, localized saccular outpocketings, one of which was just beyond the innominate vein and definitely pressed on and narrowed the bronchus to

the left lower lobe. The bronchial tree in this lobe was diffusely dilated. The bronchi were plugged with partially inspissated mucous secretions, and the lobe itself was diffusely atelectatic. The gross appearance of the aorta was characteristic of syphilis, although the process did not extend quite down to the aortic annulus. There were also two rents in the intima of the thoracic aorta, not associated with either of the saccular aneurysms. One of these was quite small and contained a small partially organized blood clot. Beneath the larger rent there was an area of apparent dissection 5 or 6 cm. long filled with partially organized blood clot, some 2 cm. in thickness. On microscopic and gross examination it seemed apparent that this was not a true dissecting aneurysm, which always occurs within the media of the aorta, but a pseudodissection between the outer border of the media and the adventitia—a type of lesion that could occur with rupture of either a syphilitic or a sclerotic aneurysm. The microscopic sections were quite interesting. There were areas presenting all the accepted criteria of syphilitic aortitis, focal destruction of the elastica and muscularis and marked infiltration with lymphocytes and plasma cells in the areas of scarring and also in the form of cuffs around the vasa vasorum. In another part of the aorta there was also characteristic media necrosis cystica, which is the cause of the great majority of dissecting aneurysms. According to standard teaching, syphilitic aortitis and media necrosis cystica are not supposed to exist together in the same aorta. I think that there is no question that in this case they did. It is even conceivable that this was true dissection, although our decision was that it was not. After careful study we found nothing that clearly explained the acute terminal episode. There may have been a little more hemorrhage in the aortic wall, which we could not clearly separate from the previous bleeding. It is quite clear that the majority of the leakage must have occurred at the first attack rather than at the second.

DR. WILLIAMS. What about the heart?

DR. MALLORY. It was normal. There was not much evidence of chronic passive congestion. The lungs weighed 1100 gm. and were moderately edematous. The liver, spleen and kidneys did not show passive congestion.

is significant. Such a difference may result from aortic aneurysm, and it is sometimes seen in dissecting aneurysm of the aorta.

DR JAMES R. LINGLEY: There is marked dilatation of all the thoracic aortic shadow extending up over the arch and down in the descending portion. The heart shadow appears to be enlarged, and there is density at the left base. In this oblique view there appears to be pressure on the left main bronchus. Another thing that I should like to draw attention to is that the calcification in the arch of the aorta has a peculiar rim—instead of being in the periphery it lies 1.5 cm. within the shadow.

DR BLAND: Could that be due to the position of the patient?

DR LINGLEY: I do not believe so.

DR WILLIAMS: Is the left bronchus elevated?

DR LINGLEY: It seems to be compressed.

DR WILLIAMS: The early symptoms described before admission certainly suggest, more than anything else, expanding aneurysm of the aorta. There is really nothing inconsistent with that diagnosis except perhaps the long period of survival following the onset of early symptoms, which is unusual for a syphilitic thoracic aneurysm. If the patient had had thoracic aneurysm on a syphilitic basis it would be reasonable to assume that the chest pain resulted from sudden expansion of such an aneurysm. The earlier symptoms of blood spitting, pain in the chest and so forth are classic.

Dissecting aneurysm, of course, should not be overlooked. Cases have been reported in which the patient survived the initial dissection for many years. I am not quite clear about Dr Lingley's statement of the inner lining of the shadow with calcium, unless it means that the original coat of the aorta was covered over with blood clot. I suppose that that could happen in a leaking saccular aneurysm of the aorta or dissecting aneurysm as well, in the former, blood might infiltrate the outer adventitia. In considering the possibility of dissecting aneurysm, one might quibble over the time of survival following the symptoms that led to admission. Several days elapsed, but it is not too incompatible with dissecting aneurysm for the patient to survive several days before death finally supervenes. From the evidence, I favor a slowly expanding thoracic aneurysm rather than a sudden dissection. It is also possible to have a dissecting aneurysm complicating syphilitic aortitis. Such cases have been reported, in spite of the fact that syphilitic aortitis is supposed to have an annealing action, theoretically effective in preventing dissection. Against the diagnosis of syphilitic aortitis in this case is the patient's sex. The ratios of male to female vary from 5:1 to 8:1, depending on the series recorded. Of course, that is not of importance as a deciding point, nor is the age against the diagnosis of syphilitic aneurysm. The negative blood

Hinton reaction is disturbing but is not final evidence against syphilitic infection. The original process could have burnt out or the test may have been negative because of the so-called "zone phenomenon." If the patient had syphilis it was more probably a burnt-out infection.

During the hospital stay the temperature rose to 100 and 101.5°F daily. Apparently, the house staff was not impressed with the possibility of coronary insufficiency or myocardial infarction to explain the more recent symptoms, because they allowed the patient to go home after a week in the hospital. Nevertheless, I think that this is a possibility, in spite of the apparently normal electrocardiogram. Sometimes, more than a week elapses between the onset of infarction and appearance of the classic changes in the electrocardiogram—as long as three weeks may elapse before a definite diagnosis is possible. I am unable to explain the fever except possibly as a result of myocardial infarction, which would also be consistent with the rapid sedimentation rate.

At the final admission eleven days later, the patient had a smothering sensation and difficulty in breathing followed by coughing, but nothing is said about the character of the cough. There was a slight drop in blood pressure. At this point something else had happened. She developed acute dyspnea and venous engorgement, and the liver was palpable. The best possibility to explain that is congestive heart failure. On that basis, the only explanation we have found so far is myocardial infarction. Another possibility is that this was not heart failure. With aortic aneurysm, especially one involving the arch, it is possible to have obstruction in the venous system supplying the neck and upper extremities by expansion of the aneurysm. If we consider that the acute pain before entry was produced by expanding aneurysm, which is possible, venous engorgement may also have been caused by the same thing. Slightly against that supposition is the fact that no dilated veins were described over the rest of the chest. As a rule, with such complete obstruction, the whole upper venous system becomes distended. If the liver had been enlarged because of venous obstruction, however, that would mean obstruction of the lower systemic venous circuit as well. Such widespread increase in venous pressure is oftener the result of congestive heart failure than of mechanical obstruction.

One other question I should like to bring up regarding the aneurysm is whether this could all have been caused by arteriosclerosis. Arteriosclerotic aneurysm of significant size is more frequently seen along the course of the abdominal aorta than in the chest, although I believe that such aneurysms have been found in the chest. I do not recall ever seeing one that produced a significant mechanical effect by expansion, but I suppose that that is another possibility that must not be overlooked as

one of the most valuable agencies that the people of Massachusetts possess

It is common knowledge that modern, universally accepted public-health methods include keeping schools open during epidemics, except under certain specific circumstances, enlightened health and school officials believe that the safety of children is better guarded by having them under daily surveillance rather than running at large. Furthermore, common sense leads to the conclusion that the public is better served by having its confidence in its deserving public-health servants strengthened, rather than disturbed, by indiscriminate alarms and uninformed criticism. Massachusetts is fortunate in possessing a department of public health with an able, honest and experienced personnel, and Newton has an outstandingly capable health officer. Any attempt at discrediting either of them must be considered as subversive of the public welfare.

The physicians of the Commonwealth should accept the responsibility of maintaining public confidence in these agencies and will no doubt be aided in the task by so honest a journalist as Mr. Cunningham when he realizes the harm that his temporary aberration may have caused.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

DWYER—William J. Dwyer, M.D., of Boston, died September 30. He was in his sixty-fourth year. Dr. Dwyer received his degree from Tufts College Medical School in 1905. He was a fellow of the American Medical Association. His widow, a son and a daughter survive.

HOLBROOK—Bradbury Holbrook, M.D., of Waltham, died August 24. He was in his seventy-fifth year. Dr. Holbrook received his degree from University of Pennsylvania School of Medicine in 1899. He was a fellow of the American Medical Association.

HOLT—William L. Holt, M.D., of Amherst, died October 18. He was in his sixty-eighth year. Dr. Holt received his degree from Harvard Medical School in 1905. His widow, two sons and two daughters survive.

PULSIFER—Walter H. Pulsifer, M.D., of Whitman, died September 26. He was in his sixty-third year. Dr. Pulsifer received his degree from Tufts College Medical School in 1908. He was president of the Plymouth District Medical Society and a fellow of the American Medical Association. His widow and three sons survive.

TERRY—Theodore L. Terry, M.D., of Stow, died September 28. He was in his forty-eighth year.

Dr. Terry received his degree from University of Texas School of Medicine in 1922. He was assistant professor of ophthalmology at Harvard Medical School and was a member of the American Academy of Ophthalmology and Otolaryngology, American Ophthalmological Society, Association for Research in Ophthalmology and New England Ophthalmological Society, and a fellow of the American Medical Association.

His widow survives.

MISCELLANY

HARVARD SCHOOL OF PUBLIC HEALTH

Expansion of Harvard University's School of Public Health through two important faculty appointments and the institution of two new degrees in research were recently announced by Brigadier General James S. Simmons, dean of the school. Those joining the staff are Dr. Hugh R. Leavell, formerly assistant director of the Division of Medical Sciences, Rockefeller Foundation, and Dr. John C. Snyder, former member of the United States Typhus Commission. In addition to degrees that presuppose the qualification of Doctor of Medicine, the school has added the degrees of Master of Science in Hygiene and Doctor of Science in Hygiene, which are open to research workers. Thus the investigation of problems connected with public health, as well as instruction, will be augmented. Dr. Leavell will occupy the chair of public-health practice, which became vacant in July owing to the death of Dr. Edward G. Huber. Dr. Snyder has been appointed professor of public-health bacteriology, a new chair created by the reorganization of the school.

When the United States Typhus Commission was organized during the Second World War, Dr. Snyder was appointed as a member. As such he studied typhus fever at close range in the Middle East and Italy. Since his release from the Army in 1945 he has been in charge of a program of typhus investigation sponsored by the International Health Division.

YALE INSTITUTE OF OCCUPATIONAL MEDICINE AND HYGIENE

Dr. Francis G. Blake, dean of the Yale University School of Medicine, recently announced the establishment of the Institute of Occupational Medicine and Hygiene for work in the field of industrial medicine. The institute, Dr. Blake revealed, will be headed by Dr. Ronald F. Buchan, newly appointed assistant professor of industrial medicine. The primary aims of the institute, according to Dr. Blake, are four in number: the training of medical students and industrial physicians, based on the belief that occupational medicine and hygiene now comprise a specialty, special graduate instruction, together with the opportunity for research in the field of occupational medicine and hygiene, which will be available to graduate students in medicine, nursing, public health and engineering, research in occupational medicine and hygiene, in the belief that the maintenance of active research in such an important field is of teaching value to the intelligent student, and consultation, whereby the institute will assist industrial concerns on certain practical questions in the same fashion as the clinicians in the School of Medicine assist their colleagues with regard to medical, surgical or public-health problems. The establishment of the Institute was preceded by nearly six years of planning and investigation, conducted on the premise that Connecticut, although relatively small in area, is one of the great industrial states and therefore has real need for work in the field of industrial medicine.

The program will be supervised by a special committee composed of the following members of the Yale Faculty: Dean Blake, serving *ex officio*, Dr. William T. Salter, professor of pharmacology, Dr. George M. Smith, research associate in anatomy, Dr. Ira V. Hiscock, professor of public health, and Dr. John R. Paul, professor of preventive medicine. This committee will serve as the co-ordinating group that will work with Dr. Buchan, the clinical director, in plan-

GREATER BOSTON COMMUNITY FUND

THE drive to raise the \$7,000,000 necessary to support the 1947 needs of the three hundred and thirty Red Feather hospitals and health, youth and social agencies is now in full swing. The question that lies squarely before the people of Greater Boston, according to Mr. John E. Lawrence, chairman of the campaign, is as follows: "Are we going to enable the Red Feather Services of the Greater Boston Community Fund to carry on those humane activities that have made this community renowned for its social consciousness?" The alternative, as Mr. Lawrence points out, is a sharp curtailment of essential services or their maintenance on a bare minimum-need basis—either of which is unthinkable.

The total that must be raised is nearly as large as those of the war years, in spite of the fact that support of certain agencies engendered by the war has been withdrawn. This, however, is not surprising when it is realized that the costs of food, wages and deferred maintenance have increased by at least 40 per cent. "The challenge is put to every one of us," declares Mr. Lawrence. "I firmly believe that the decision will be to keep the community strong. It is up to all of us to force that decision, and I call on every worker and every giver to do just that. We must RING THE BELL!"

A REGRETTABLE INCIDENT

It is unfortunate that "Bill" Cunningham, justly celebrated columnist of the *Boston Herald*, should have abandoned all restraint in his column of October 27 that commented on the recent postseason outbreak of poliomyelitis in Newton. At the time of the appearance of this article, 12 cases of infantile paralysis had appeared in that city since October 1, of which 9 had occurred in a certain school district. The school in question had not been closed on account of the outbreak, and this apparently seemed to Mr. Cunningham to have been a dereliction in duty on the part of city and state health authorities and aroused his sense of personal responsibility to the public. Possibly he was somewhat "hyper-sensitive" to the matter because of certain broad comments he had only recently made concerning pollution of the Merrimac River with poliomyelitis virus, a statement in support of which evidence is still lacking.

Regrettably, Mr. Cunningham in his investigation appears not to have used the probe but rather the bludgeon, and to have become inflamed at, rather than appreciative of, the methods of the highly trained officials who constitute the health departments of both the Commonwealth of Massachusetts and the City of Newton. It is with little real insight into the problems and the difficulties of public-health administration that Mr. Cunningham allowed such a statement as "Health Guardians Need Lesson in Humility to Public, Parents" to appear over his signature, it is unworthy of this protagonist of the common good to attempt to discredit

MEDICINE IN THE POSTWAR WORLD*

MORRIS FISHBEIN, M.D.†

CHICAGO

IT IS well known that medicine in the postwar world will be far different from what it was at the end of World War II. The many advances, the great economic changes in the condition of peoples all over the world and the difference in the planning and organization of civilization make it folly to believe that in the years to come the status quo can be maintained or the life of previous generations enjoyed. A list of the discoveries that came out of the war through the co-ordinated and integrated research that was carried on reveals at once the great changes that have occurred in the practice of medicine. Unfortunately, medicine knows far more about the changes than the people, who benefit by the progress.

In World War I, 24 per cent of the soldiers who developed pneumonia died, whereas in World War II, less than 0.5 per cent died. That is, of course, a tremendous fact and an indication of the discovery and application of the sulfonamides, the antibiotics and penicillin, as well as a representation of the extent to which a significant discovery alters the entire picture of medical practice more than any amount of organization, administration or legislation.

An example is afforded by the change in the control of venereal disease, particularly as a result of new methods of treatment employing the antibiotic drugs. For more than a hundred years, in efforts to stamp out venereal disease, millions of dollars of federal money have been expended in the United States, without conspicuous success. Yet it is safe to predict that an application of the newer knowledge of control that has resulted from the war—the treatment of gonorrhea by the sulfonamide drugs and the intensive therapy of syphilis by the use of penicillin and heat and the newer arsenicals—will, within a quarter of a century, render these two venereal diseases as rare as typhoid fever and diphtheria are today. The progress in the control of typhoid fever and diph-

theria in the last fifty years was accomplished not by the spending of vast sums of money, by the invoking of the police or military powers of the nation or by the passing of new legislation but by invention and discovery in the field of medicine and particularly by the high state of knowledge developed by the medical profession.

Americans are proud of the fact that in the United States medical education leads the world. In no other country do medical schools approach the standards achieved by American institutions, nor is medical research in other countries comparable. There are no hospitals capable of rendering a higher quality of medical service than that furnished by the hospitals of the United States. It is therefore probable that physicians all over the world, for the next generation, if not for the next hundred years, will look to and will visit the United States in search of the benefits achieved by the advance of medical knowledge.

In World War I slightly over 9 per cent of men with wounds of all types died, in World War II less than 3 per cent died of their wounds. In World War I, chest wounds were fatal in 70 per cent, in World War II, in the Army of the United States, 20 per cent—but in the German Army 70 per cent—of men wounded in the chest died of their wounds.

These well established statistics bear testimony not only to the great discoveries in the treatment of injuries and disease but also, of course, to the quality of medical knowledge and medical practice in the United States. It is true that the application of blood transfusions and blood plasma and the various derivatives of blood, many of which had already brought about great changes in the control of diseases of various types, played a vital part in the saving of lives from shock and hemorrhages. It is also true that the antibiotic drugs eliminated the secondary infection associated with wounds of the chest and abdomen, but Dr. Kirk, Dr. McIntire or any of the great medical leaders of the armed forces of the United States would give the credit not only to these drugs but also to the high quality of surgical work and to the fact that such

*Presented at the annual meeting of the New Hampshire Medical Society, Manchester, May 14, 1946.
†Editor, *Journal of the American Medical Association*.

ning the work of the institute at the inauguration of the program. Dr Buchan, who will sit with the committee, has been practicing industrial medicine in Hartford, where he has been concerned primarily with the organization of medical services for a group of small industrial plants

BOOK REVIEWS

What People Are. A study of normal young men. By Clark W Heath, M.D. In collaboration with Lucien Brouha, Ph.D., Lewis W. Gregory, Carl C. Seltzer, Ph.D., Frederic L. Wells, Ph.D., and William L. Woods, Ph.D. A publication of the Department of Hygiene, Harvard University, under a grant from the Grant Foundation. 8°, cloth, 141 pp., with 7 tables. Cambridge: Harvard University Press, 1945. \$2.00.

This book is the result of the study of students at Harvard University, begun in 1938. The author, in collaboration with his colleagues, made a study of over two hundred and fifty young men from various points of view. It was not easy to pick out the "normal," for in the first hundred supposedly healthy men studied, seventy-two requested some sort of advice and another twenty-two presented urgent problems, mostly on the basis of a choice of a career, social adjustments or personality difficulties. An attempt was made to study the normal personality and the degree of adjustment to college life — as illustrated by athletic participation and their problems concerning religion, sex and other matters. Physiologic and mental measurements were made, and general medical problems were also investigated. This report discusses various aspects of these problems and is a valuable addition to knowledge in this field. It is only a preliminary study and should lead to more extensive research. The material presented, however, is of interest to physicians, particularly those associated with colleges, and to sociologists, educators and psychiatrists.

Lights Out. By Baynard Kendrick. 8°, cloth, 240 pp. New York: William Morrow and Company, 1945. \$2.50.

This is the story of a soldier in World War II from the time he was rendered totally blind by a sniper's bullet, until he was completely conditioned to take his place in the world of today. The psychology of the blind veteran is vividly portrayed, and interesting and accurate descriptions are given of the therapy and methods of rehabilitation practiced at the Valley Forge General Hospital, Pennsylvania, and the Old Farms Convalescent Hospital, Avon, Connecticut. This novel is an important contribution to the medical history of World War II.

Government in Public Health. By Harry S. Mustard, M.D., LL.D. 8°, cloth, 219 pp., with 11 tables. New York: The Commonwealth Fund, 1945. \$1.50.

This monograph was prepared at the request of the Committee on Medicine and the Changing Order of the New York Academy of Medicine. The letter of invitation read: "What is wanted is not merely a survey of the present situation, but knowledge of how it came to be, perspectives to help chart the direction of future developments."

The scope of public health is outlined, federal health services, state health departments and local health departments are described, and future trends are discussed. The following quotations from the book describe its contents:

First, there has always been, and there is now more than ever, a trend toward a more powerful federal government and, second, there has recently developed a strong trend toward a more socialistic federal government. Pertinent in this connection is the fact that public health activities are more and more being considered as an integral part of the developing social security program and are receiving increasing federal attention.

This document is to recognize political and social evolution as it relates to the public health, to view these things as nearly objectively as possible, to regret the passing of earlier concepts and manners, and to confess to a belief that a better public health will result from the changing order.

To those who do not approve of some of the social and governmental trends of today, it is suggested that it is

more profitable to recognize their enemy's approach and dimensions than it is just to swear at him after being blinded by temper.

This volume should be read by members of the public health profession and will be a valuable addition to the library of practitioners of medicine.

NOTICES

ANNOUNCEMENTS

Dr. G. Burnham Beaman announces the removal of his office from Boston to 322 Main Street, Stamford, Connecticut, and the inauguration of a psychiatric service and outpatient clinic in psychiatry at the Stamford Hospital.

Dr. Paul J. Catinella announces the opening of his office for the practice of dermatology and syphilology at 520 Commonwealth Avenue, Boston.

Dr. Samuel H. Marder, having returned from military service, announces the opening of his office for the practice of psychiatry at 419 Commonwealth Avenue, Boston.

Dr. Bernard Yood, recently discharged from military service, announces the opening of his office at 481 Beacon Street, Boston, for the practice of psychiatry and neurology.

EDWARD K. DUNHAM LECTURES

The Faculty of Medicine of Harvard University has announced that the following lectures on the general topic "Biochemical Lesions and British Anti-Lewisite" will be delivered by Dr. Rudolph A. Peters, Whitley Professor of Biochemistry, Oxford University, under the Edward K. Dunham Lectureship for the Promotion of the Medical Sciences.

Monday, November 18 The Significance of Biochemical Lesions

Wednesday, November 20 The Arsenical Lesion and its Antidote

Friday, November 22 Clinical Applications and Developments of BAL

These lectures are scheduled for 5 p.m. at the Harvard Medical School, Building C Amphitheater.

NEW ENGLAND SOCIETY OF PHYSICAL MEDICINE

A meeting of the New England Society of Physical Medicine will be held at the Veterans Hospital, West Roxbury, on Wednesday, November 20, at 8:30 p.m.

PROGRAM

Clinic on Physical Medicine with Case Presentations

Dr. Jacob Rudd

Medical Rehabilitation in the Veterans Administration

Dr. Sidney G. Licht

Discussion: Dr. Arthur L. Watkins

CANCER TRAINEESHIPS

Dr. Thomas Parran, surgeon general of the United States Public Health Service, Federal Security Agency, has recently announced that the National Cancer Institute, which operates as a division of the National Institute of Health, has funds to train approximately thirty physicians in the diagnosis and treatment of cancer. Under a federally financed program, doctors wishing to specialize in this field may be appointed as trainees and be assigned to authorized nonfederal, nonprofit institutions in various parts of the country. Applications for traineeships should be sent to the Director, National Institute of Health, Bethesda, Maryland.

(Notices continued on page xxi)

the specific request of President Roosevelt, to rehabilitate 2000 men, rejected because of such conditions as hernia and flat feet, sufficiently to render them capable of physical service in the Army. I assure you that the total number of men made available by that particular technic did not justify the extension of the project on a nationwide scale. Such figures and facts have never yet been presented at the hearings before the Senate Committee on Education and Labor.

In the period before the war, the Nation was well hospitalized, and it was accepted that 5 beds per 1000 people were adequate for any community. As a result of the advances in medical science, the new technics in surgery brought about by cyclopropane and basal anesthetics and the application of the antibiotic drugs, there is no longer the need for the number of hospital beds once demanded for a community of any size. It is now estimated that 35 beds per 1000 people instead of 5 provide adequate hospital facilities for a community. That is because, from 1912 to 1919, a patient entering a hospital for an operation for appendicitis could reasonably expect to spend fifteen to nineteen days in the hospital, whereas today the average stay is nine days, in many institutions, women who were formerly confined to bed for fourteen days after childbirth are now permitted up on the second or third day and plan to leave the hospital on the tenth day. Most of this change has been effected by the use of physiotherapeutic methods, amino acids and the vitamins, preoperatively and postoperatively, which also represent the advance of scientific medicine and the application of scientific methods under the best possible conditions, as well as the high state of medical education in the United States.

In considering postwar medicine, one must envision a still wider extension of the facilities of high-grade medical education to more and more people of the country. At the present time there are seventy Class A medical colleges and five new Class A medical colleges that are either opened or in process of being opened. With these new developments, I am quite sure that the schools in the New England states will be still further extended, and that high-grade medical education will be open to more and more young men who want to fit themselves for a career of service to mankind, with a reasonable amount of prestige and dignity, again provided that the legislators are not so shortsighted as to make it undesirable for a young man to seek a career in one of the greatest professions the world has ever known.

As I look over at what is happening in Great Britain, I shudder for the future of medicine there. The nation proposes to take over — in the old sense in which Al Capone used to "take over" — the medical profession and the hospitals, which will be administered as state institutions. So far as the

physicians of Great Britain are concerned, when the Minister of Health was asked what the income would be in the future, he replied, "A physician may reasonably expect to earn an income of \$5200, and after twenty years he may reach \$7200." That is the future offered to the physicians of Great Britain when the new health act proposed by the Ministry of Health becomes effective — if it ever does become effective. Because I am certain, knowing the people of Great Britain as I believe I know them, that, after five or ten years of what will happen to medicine under such a scheme, there will probably be a reversal of sentiment as great as that in other countries that have destroyed their own medical professions.

At this point, I wish to pay tribute to the industries associated with medicine in the United States. In a recent publication written by John Langdon Davis, of the British Bureau of Information, great tribute was paid to the pharmaceutical industry of the United States, which bears much of the prestige and honor for the winning of the war, because of its magnificent job of mass production that resulted in the saving of the health and lives of the soldiers and sailors of Great Britain, Russia and China, as well as of Americans. This achievement was made possible by the mass production of penicillin in this country in which twenty-three industries produced the drug at a rate that would have been inconceivable had not this great genius for mass production been applied. I remember sitting in on the first conference on penicillin with Dr. Florey at the National Research Council in Washington, where American manufacturers predicted that in three years 400 million units of penicillin a month might be produced. Last month, more than a billion and a half units of penicillin was produced. That means that the United States today is serving all the world with that antibiotic drug. No other country, including Great Britain, which has most of the honors for the discovery of penicillin, has even approached that level of mass production. Brazil and France are still trying to produce it in amounts of two quarts, we are producing it in ten-ton tanks. That is the difference between the genius of mass production of the United States and that of other countries. More factories are now being built, at a cost of millions of dollars, for the production of streptomycin, and such American advances as blood and blood derivatives, streptomycin, penicillin, DDT, Atabrine and 6718 for malaria mean that for at least a generation no other country can hope to approximate, much less equal, the progress of the United States in the advance not only of medical science but also of the industries associated with medicine.

This progress means little to the American people, unless its fruits can be made freely and generally available to all who require them. No one wants more than the doctors of the United States and the

excellent medical and surgical care was available even in the front lines

That is a testimony to the 60,000 American physicians who left their practices and the work they had built up for many years and entered the service. In 1940 there were over 180,000 physicians in the United States, of whom 150,000 were licensed to practice, and of those actually in practice 60,000 went out from their homes, offices and hospitals into the service of the Army and Navy. Today, something like 32,600 doctors have already been discharged from the Army and 6700 from the Navy. That means that about 40,000 of the 60,000 are now returning to their homes and communities to take up the work they left four years ago. It should be remembered that these men are returning to homes that have been broken up, to offices that have been taken up for other purposes and to communities in which the motor car and the facilities of medical practice have to some extent been eliminated. It must therefore be recognized that, overnight or in a year or two, the kind of medical practice that was generally available in the prewar years cannot be restored. Before the war there was 1 doctor to every 700 people, today, there are at least three counties in the United States in which there is only 1 doctor to more than 10,000 people. It is obvious, of course, that under those circumstances the medical care of the nation will suffer from a considerable number of inadequacies. It is unfortunate that the politicians and particularly the demagogues, who are endeavoring to lead the American people into strange ways of life far remote from the traditions of American democracy, should take advantage of unsettled conditions, which are clearly the result of war, and of inadequacies that everyone freely admits to bring about fundamental and complete medical changes in the United States. In promoting the proposed changes, they take advantage of strange statistics of one kind or another that are the height of folly and humor and would be so considered if the ultimate implications were not so serious.

Dr. Bauer has referred to the statistics of Selective Service, and I suppose that in all the hearings that have been going on in the last six weeks before the Senate Committee on Education and Labor (and I hope that some of you have been reading the condensations of the hearings) the proponents of these fundamental and revolutionary changes have repeatedly called attention to the amazing and shocking statistics that, they believe, should startle the Nation into a complete revolution in medical care. They have no real interest in the kind of scientific evidence that the medical profession demands as a basis for any new change or complete revolution in medical practice. To prove their statements of "amazing" and "shocking," they cite such round numbers as the 40 per cent of men in the United States who were rejected as physically

unfit. They say nothing whatever about the obvious fact that, in the first attempt to obtain an army for Selective Service before entry into the war, the highest standards of physical fitness developed for any army in the world at any time were employed. It will be remembered that at first the requirement for teeth was six good teeth in the upper jaw and six in the lower jaw and that it was later determined that the teeth had to be opposite each other. On that basis, 20 per cent of the men examined were rejected before the standard had reached the stage of merely counting the number of teeth in the jaws. Of course, it is quite impossible, if an Adonis is set up as the standard of physical fitness in men, to select a considerable number of people, or to pick out a considerable number of women if a Venus is the criterion. I believe that I should even have a little difficulty in this audience to reach that standard of physical perfection. Yet that was what was attempted in the Army when Selective Service was first in effect.

It is the humor of a nation that really reflects the nation's point of view. Before V-J Day, it was frequently stated throughout the country that if a boy who came up for the draft was still warm, he was in. And that represented, of course, the changing standards of physical fitness that ultimately came about. And it should be borne in mind that the statistics that are being cited before the Congressional hearings are actually the analyzed statistics of the first 2 million men — out of a total of 19 million examined — who came up for examination in 1940 and in the early portion of 1941. The statistics of the war years offer an entirely different picture.

During the first portion of the war, 4 million men, of the total of 19 million examined, were rejected, including 800,000 illiterates — 800,000 men who never reached the fifth grade, in a nation in which public education is free, and in which public education in many areas is compulsory, as compulsory and as free as health care would be under the changes proposed. At the end of the war, I visited the Great Lakes Naval Training Station to see 600 men, formerly classified as illiterate but subsequently taken into the United States Navy, who lifted up a certain amount of garbage into a shovel and deposited it in a wagon, they performed the task efficiently, whether or not they were illiterate. And so, everything depends on one's standards. We should make clear to our senators and representatives that it is the standard by which one measures that determines one's condition.

Again, I should like to point out that early in the war, when I was at one time adviser to the Selective Service and associated with many of the committees set up by General Hershey, a pilot experiment was conducted covering the states of Maryland and Virginia, in which it was endeavored, at

and the CIO, but it got space. Most of the members of this audience know in a general sense about the National Health Program. But, if I were to ask what were the five points, since this is not "Information Please" evening, there might be some difficulty in making a reply. Perhaps I can get Clifton Fadiman to ask his experts some night to name the five points of President Truman's health program, the experts would probably know that it had something to do with compulsory sickness insurance, and they would not know the other points. There are four additional points to the program, however, and it is highly significant that the medical profession of the United States has given its wholehearted approval to them.

The medical profession favors the widest possible extension of medical facilities in the form of hospitals, diagnostic centers and health centers, so that a high quality of medical care can be available, wherever there are enough people to require a hospital or a diagnostic or health-center service. There are, of course, certain areas in the United States that could not possibly build or maintain for themselves even small institutions of the type proposed. It is well within the province of the Government to make the funds obtained from taxation available for the extension of such a program. The American Medical Association has approved Senate Bill No. 191 (the Hill-Burton Bill), which was passed by the Senate and is now in hearing before the House and is likely to become law. That bill will make available 5 million dollars a year for administration and 75 million dollars a year for adequate buildings and diagnostic centers. All a state has to do is to have the governor determine the number of hospital and health centers available and needed and make the required survey. The governor then applies to the proper board, which will have charge of the funds under the Hill-Burton Bill, to obtain the state's share of the appropriation. The bill is bound to result in a greater number of health centers than heretofore. Fourteen states, in anticipation of that legislation, have already appointed committees or boards to undertake the surveys, and as soon as the act is passed, their applications will be submitted.

In Oklahoma, the entire area of the state has been mapped out, with a dot on the map for every health center, district hospital and diagnostic institution required. The project will be developed about a great medical center in Oklahoma City, with a large hospital in association with the medical school that will be highly specialized in the fields of neuropsychiatry and infectious diseases, and there will be a children's hospital and a maternity hospital, all part of the educational center. The most remote areas of the state will be able, under the freedom and initiative of the medical

profession working with the government of the state, to set up a medical system in association with a voluntary hospitalization and sickness insurance system that will effectively blanket the state. Oklahoma is in the nature of a frontier state, but I am quite sure that many of the older states could do an equally good job, and I believe that more than fourteen states have already set up committees in anticipation of this type of service, of which, of course, organized medicine approves. That is the American way — the acme of the use of the voluntary service and the private initiative of the people to achieve desirable results.

Half the states do not have a public-health and preventive medical service, perhaps all of them do not need it. Dr. Bauer has pointed out that in some communities there are extremely few people, so that to maintain a health officer would be utterly foolish — all he would have to do would be to keep a census of the people he started with. In such a situation, of course, a medical center is unnecessary. A preventive medical district center within certain states will be required, however, to provide a proper preventive medical service covering a total number of people, rather than an area. Suitable technics will have to be worked out. Federal funds, under the extension of the existing Social Security Act, may be required to meet the need. Again, under the Emergency Maternal and Infant Care Bill, there could be under certain circumstances a considerable number of mothers who did not receive post-partum care in childbirth — I do not know the exact number. At the present time in the United States, 80 per cent of white women have children delivered in hospitals, the number among Negroes is considerably less. Sooner or later, a technic must be worked out providing for adequate prenatal care, delivery and post-partum care that will repay the nation in healthy mothers and children.

Maternal death rates have dropped in the United States almost unbelievably. Fifteen years ago, in Wisconsin, there were 400 maternal deaths a year, today, although there is a 15 per cent increase in population, there are only 100 maternal deaths a year. Such figures show what can be and has largely been accomplished by improvement in obstetric service, not under state control but through the advances in obstetrics, with the new knowledge regarding the use of narcotics and their effect on the avoidance of toxemia and eclampsia — all of which has resulted from the voluntary service of physicians, working in hospitals and carefully and scientifically recording the results.

But try to explain that to Senator Pepper. He has no background in the field of obstetrics — of that, I am reasonably certain. Nevertheless, he comes forth with a bill providing that every woman in the United States shall be entitled to complete obstetric care when she asks for it and, in addition,

associated professions to see the widest possible distribution of medical care. If it is necessary to create more organization in medicine, at the same time retaining the features of medical science that comprise its greatness, the medical profession, which has led in the organization of medicine in the United States above all other nations in the world, should be given a reasonable opportunity to develop the kind of organization that can deliver a high grade of medical practice under the conditions of a democracy.

I have bragged somewhat about medical organization in the United States. In what other nation in the world is there a profession that contains a membership like that of the American Medical Association, in which 127,000 out of 155,000 practicing physicians are represented? What other organization has produced anything resembling the publications of the American Medical Association? What organization anywhere in the world has produced the kind of services rendered by the bureaus and councils that standardize medicine on an exceedingly high scale? Drugs and chemicals have been standardized through the councils, which, by defining quality and wholly by the power of public opinion, have raised the standards of pharmaceutical products in the United States above those prevailing anywhere else in the world.

In the United States there are a considerable number of the sulfonamides, such as sulfapyridine, sulfathiazole and sulfaguanidine, there is one name for each type, and it is recognized that the drug will be known by that name. In England there are forty-seven different names for sulfanilamide, each one of which is presumably known to each doctor, so that he can choose the particular one that he wants to work with, there is nothing resembling the standardization of pharmaceuticals that obtains in this country. Through the Council on Foods and Nutrition, the American Medical Association has standardized the use of food products and has maintained rationality in the gradual development of the use of vitamins. The use of physical apparatus has been standardized, so that there is none of the quackery and charlatanism that prevail in many countries.

The Council of Medical Education and Hospitals has established criteria for medical colleges and hospitals. The American College of Surgeons protects the patient against the hospital and the surgeon, if need be, by the work of men in the field of pathology, who carefully collect these data, to provide a rational and scientific basis for surgery.

It is the desire of organized medicine to deliver a high quality of medical service, and the Council on Medical Service proposes to set up the standards for such service voluntarily ensuring the patient medical care of a high quality, which he has purchased. Unless such standardization under insured systems prevails, there will never be a

high quality of medical service. I am convinced by all the available evidence that if ever a nationwide system of compulsory sickness insurance, administered out of a single type of Social Security Board, should be inflicted on the people of the United States, an unprecedented deterioration in the quality and a breakdown in the ethics and delivery of medical service would ensue. The scandal and deterioration in the quality of medical service delivered to veterans in the United States under the previous Veterans Administration give an indication of what eventually occurs when medical service that ought to be personal, ethical and possessed of a high morale is subjected to the routine work and clock-watching activities that are invariably a part of that kind of medical service. One of the greatest services rendered to scientific medicine was the exposition of what happened to a centralized, bureaucratic control in the Veterans Administration, so that the people of the United States might know what to expect.

Medical practice in the United States in the postwar world offers the opportunity to apply medicine of a high type, developed in the highest quality of medical education and institutions and extended to all the people. Such an opportunity, to a scientist, entails some sort of diagnosis of the areas of need and the nature of the treatment to be applied when the area is determined. In the United States, of course, there are considerable inequalities in the nature and distribution of medical service. For instance, the two highest death rates for tuberculosis, if properly localized and focused in the areas of great need, are not among the Negroes in the South but among those in Newark and Chicago. Obviously, if the death rate from tuberculosis is to be lowered, attention must be focused largely, to begin with, on those particular spots.

It is known that when Wassermann and Kahn tests were conducted among the students of the University of Minnesota, 0.25 per cent showed syphilis. But similar tests on every inhabitant in certain Negro sections of the country showed a 33 per cent incidence of syphilis. Obviously, an attack on the problem of syphilis must begin in the area where it is 33 per cent prevalent, and not where there is an incidence of 0.25 per cent. If the area of need is determined and the remedy applied, a reasonable return on the investment can be expected. That, of course, is what is needed in the United States, to approach the problem from that point of view, the medical profession has already given all the aid it can to certain legislation that seems necessary for progress. Some time ago, Mr. Truman went before the Congress for the first time as President with what was called a "National Health Program." The program was mentioned in the press and on the radio—it did not receive as much attention as John L. Lewis

worker, who is promised health service over which he will have no control, this is called health insurance. I prefer to call it taxation to enable the Government to distribute political medicine throughout the United States. In the end, the plan is nothing more than the setting up of a vast political machine.

In some countries in the world having compulsory sickness insurance, there is 1 government employee for every 100 insured persons. This bill proposes to cover 120 million of the 135 million people of the United States, so that the figure, by careful accounting, might be 1,200,000 new government employees. I do not believe that so many will be involved, Mr. Murray and Mr. Pepper have repeatedly pointed out that a considerable social-security system has already been set up, including the Social Security Board, the district Social Security agencies and the local Social Security inspectors.

But what are the Social Security employees doing now? If they have enough to do, the whole sickness care of the United States cannot be added to the present Social Security system, which in its time has had, I might say, strange inadequacies. I said to Paul McNutt one day, "I understand that you have 8 million John Doe cards." He answered, "What's that? Wait a minute. I heard you, but I didn't know you knew." A "John Doe card" is a card in the files of a government bureau to indicate that contact has been lost between a man's number and what he has coming to him, his name has been separated from his number, or he and the card have been lost altogether. At one time there were 8 million John Doe cards. Paul McNutt told me that they had worked it down to a reasonable million cards. There are therefore a million cards of this type, because the American workers move around and bookkeepers get sick and the changes are not recorded.

I told the following story to Congressman Miller.

Here's a poor fellow with a gall bladder, he has a few stones, and one of them started off and it is not getting any place. So he is disturbed, he has pain, and he is suffering. He calls in a doctor and the doctor says, "This is a little heavy for me, I shall have to get you a specialist." The man doesn't want a specialist because he has confidence in the doctor, but the doctor tells him "This is outside of my range, I've got to get you a specialist. I'll get Dr. Smith for you." Well, the patient doesn't like Dr. Smith. "But you've got to take Dr. Smith because he is the one the Social Security Board says does that type of work." That makes no difference, he does not want him. Consequently, he files an appeal with the district Social Security administrator, who has no authority outside his own district and who does not want to overrule the decision, and is told "I am sorry, but Dr. Smith is the fellow that the Surgeon-General picked, and he is your man." But the patient still does not want Dr. Smith. In the meantime, he is vomiting and he has a little pain, and the gall bladder is getting quite annoying, if he is still alive. He therefore asks the Social Security Administrator, "What can I do?" Senator Pepper's answer to that question was that the patient could appeal to the courts over the decision of the Social Security Administration. The case, which is put on the docket, will come up in the session in October of the year following the date in which the gall bladder hurts — the patient finally gets to the courts.

The time may come when the Supreme Court of the United States will spend its time trying to find surgeons to remove John's gall bladder eight years after John has been cremated!

That gives an odd picture of what medicine could come to under that kind of administration. The President and Senator Wagner stated that the bill offers a free choice of doctors, which it cannot possibly do. In the first place, there are not that many doctors. A physician is not required to work under the system unless he wishes to do so, and most of them will probably not choose to do so for quite a considerable time. In addition, a doctor's number of patients is limited. It might well happen that one of you has been chosen by the good-looking women of this town, and along comes a not-so-good-looking-woman who wants to get on his panel, which is filled. She appeals to the Social Security administrator, who tells her that Dr. — must lose one of his present patients before he can take a new one. The woman replies, "I know the aldermen," or "I know the Governor, and he will see to it that I get on Dr. —'s list." So then, someone is removed from Dr. —'s list, and she gets in on the panel. Dr. — takes one look at her and says "I don't want her anyway!"

Such a story appears comical, I am telling it to be comical. But that is how the bill will work out. For Mr. Altmeyer granted freely to Senator Donnell of Missouri that if twelve doctors in Sedalia, Missouri, refused to work under the system, preferring private practice, the Surgeon-General of the United States, since the people in Sedalia had paid their insurance or their taxes, would send in physicians to take care of them. That is totalitarianism under the guise of compulsory sickness insurance, it is the equivalent of saying that if doctors do not want to work under the system, the Government will see to it that somebody is there to take care of the people who have paid their taxes or their insurance.

The Wagner-Murray-Dingell Bill, an unfortunate piece of legislation, in my opinion — based on a considerable amount of observation and evidence — will receive an interim report. When something pretty hot comes up in Congress, an interim report is issued. The following warning is given: "You fellows keep on working, or we may slip it over on you." That is the present position of this piece of legislation, and organized medicine must continue studying and working on it. Senator Murray stated not only to me but also to some of the witnesses present at the hearings "After all, we scared you fellows so much that you have really started to do something, whereas formerly you talked about it a great deal and didn't do very much." Being an honest man, I replied, "There's no doubt about that. You scared the boys considerably. The doctors are plenty disturbed, and they are moving faster than ever be-

that every child shall have complete medical care without cost up to the age of twenty-one years. Well, that baffled me. I have a boy nineteen years old, and he has been away from home for a long time, he is taller than I am, and I should hate to call him a child. Yet a senator of the United States proposes that the Government give complete medical care to all children up to the age of twenty-one years. I have estimated, and I think the figures are accurate, that there are 40,000,000 under twenty-one in the United States. For those children, granting each one of them \$10.00 a year for medical care, \$400,000,000 a year would be required. The addition of approximately 2,750,000 women each year giving birth to children and approximately 300,000 who could but do not result in an interesting figure. Consequently, the total of approximately 3,000,000 women, with a minimum of \$50.00 per woman for ordinary care, would involve as much money as is now spent in the United States for all medical care.

The problem of the aged today is the most serious of all the problems because there are so many of them among us. I remember that in the old days when the parents grew old the children helped care for them. Sometimes they took their parents into their homes, it was considered desirable to maintain the family as the center of life. In a democracy, the family must be preserved, or democracy will perish. But here is a proposal that the family be destroyed and that the state take care of the children and of the mothers in childbirth. One can imagine in the future long lines of children proceeding in a mass-production line up to some child specialist, associated with a social worker and a nurse, who perform inoculations and tell how the baby shall be fed (God knows where the mother is!). This is a picture of the breakdown of a democracy initiated through a scheme for the medical care of the mothers. But the medical profession considers the best medical care to be that of a mother by her own physician and that of a child by the family physician, with the mother present and not delegating her responsibilities to a state-controlled or a federal-controlled institution. It is quite possible under the existing social security act to provide that type of service.

During the war, under the Office of Scientific Research and Development and its committees and the National Research Council, the great scientific discoveries that I have mentioned were developed, and those advances should be extended. Senators Magnuson and Kilgore have introduced a bill with which the American Medical Association is in complete agreement, except on minor details concerning patents that are considered to have no place in the bill. Organized medicine is in favor of the continuation of the co-ordinated and intensified research that has so far yielded vast benefits. This bill does not propose to build federal research

institutions but to make sums of money available, beginning with \$125,000,000 the first year and \$250,000,000 in five years, 20 per cent of which is to be used under the direction of a medical board, the rest under the control of a basic science board, and the defense funds under the control of a defense board. This is all to be made available in existing institutions of education, existing hospitals and existing institutions of research, where young men can gradually develop from students into the kind of research men needed for that type of service. That is the third point of President Truman's health program.

The fourth point of the program provides that workers be insured, as they are now insured against loss of their jobs, and insured as they are now protected against old age, by an addition to their insurance, with protection against loss of wages due to illness. Obviously, that is the kind of protection that every worker needs. If a worker is out of work for fourteen or fifteen weeks because of illness and his employer has not worked out a plan for maintaining or continuing his income to support his family, that has to be the man's responsibility. If workers can be taught to save in time of employment against loss of wages due to illness, even under a compulsory plan, all they are doing is putting the money in a bank for use when they need it, they are still the owners and the bosses of the money, and no federal agent is distributing the money and telling them who shall take care of them. That is a sound application of the insurance principle.

But President Truman's fifth point, unfortunately, is one on which the medical profession not only does not see eye-to-eye with him but not at all. That is his compulsory sickness insurance which he took the trouble to say five times in his speeches was not socialized medicine. We have developed new jargons associated with economics, sociology and the social sciences that are difficult for a great many people to understand. I challenge you to understand what most psychoanalysts mean by the "id," "ego" and a few of the other things that are supposed to be disturbing the people. So that when those phases of the work are involved, strange jargons are used. But it makes no difference whether the plan is called "compulsory sickness insurance" or "compulsory health insurance," as its sponsors prefer to call it. It is health insurance in the propaganda sense, since the word "sickness" would be unfavorable to the propaganda. It is sickness insurance nevertheless.

The words "preventive medicine" occur only once in the one hundred and eighty-six pages of the bill. And, of course, the plan involves not insurance but taxation, because it is taxation of the worker and the employer—you pay the taxes, they collect and keep the taxes and they spend them. That is taxation. A tax is imposed on the

THE RECEPTION IN ENGLAND OF HENRY JACOB BIGELOW'S ORIGINAL PAPER ON SURGICAL ANESTHESIA

JOHN F. FULTON, M.D.*

NEW HAVEN, CONNECTICUT

IT IS not widely known that Henry Jacob Bigelow's original announcement concerning surgical anesthesia, which was issued in the *Boston Medical and Surgical Journal* on November 18, 1846, when its author was twenty-eight years of age, was reprinted at least four times within a few weeks of its appearance—twice with the omission of the final controversial paragraphs about the patent and twice in its entirety†.

The first reprinting, which included the entire text, appeared in the *Boston Daily Advertiser* on November 19, the day after it had been published in the *Boston Medical and Surgical Journal*. Eager to convey news of the great discovery to his friend Francis Boott, of London, Professor Jacob Bigelow, young Bigelow's eminent father, wrote a letter to him on November 28, in order to get it on the first boat sailing for Europe (December 1), and enclosed a copy of the *Advertiser* for the 19th. The text of this letter, which was published in the January 2, 1847, issue of the *Lancet*, has not often been reprinted and may therefore be of interest.

Boston, Nov. 28, 1846

My dear Boott, — I send you an account of a new anodyne process lately introduced here, which promises to be one of the important discoveries of the present age. It has rendered many patients insensible to pain during surgical operations, and other causes of suffering. Limbs and breasts have been amputated, arteries tied, tumours extirpated, and many hundreds of teeth extracted, without any consciousness of the least pain on the part of the patient.

The inventor is Dr. Morton, a dentist of this city, and the process consists of the inhalation of the vapour of ether to the point of intoxication. I send you the *Boston Daily Advertiser*, which contains an article written by my son Henry, and which is extracted from a medical journal, relating to the discovery.

Let me give you an example. I took my daughter Mary, last week, to Dr. Morton's rooms, to have a tooth extracted. She inhaled the ether about one minute, and fell asleep instantly in the chair. A molar tooth was then extracted, without the slightest movement of a muscle or fibre. In another minute she awoke, smiled, said the tooth was not out, had felt no pain, nor had the slightest knowledge of the extraction. It was an entire illusion.

The newspaper will give you the details up to its date, since which other operations have been performed with uniform success.

Several authors have stated that Henry Jacob Bigelow himself went abroad in December, 1846, to bear tidings of the ether discovery, but contemporary references to him in the *Boston Medical and Surgical Journal* indicate that he was definitely in

Boston during December, many also have erroneously attributed to him rather than to his father the letter addressed to Francis Boott.

On what day Jacob Bigelow's letter actually reached London is not known, but the crossing must have been, for those days, extraordinarily quick since the first reference in the British press to the use of ether appeared in the December 18 issue of the *London Medical Gazette*. This suggests that the vessel sailing on December 1 must have arrived in England at least by December 16, for two days gives small margin for delivering the letter, — which probably arrived at Liverpool, — abstracting its contents and setting it up in type. Since the text of this first announcement has not been alluded to in recent histories on anesthesia, it is given here.

ANIMAL MAGNETISM SUPERSEDED — DISCOVERY OF A NEW HYPNOPOIETIC

We learn on the authority of a highly respectable physician of Boston, U. S., that a Dr. Morton, a surgeon-dentist of that city, has discovered a process whereby in a few minutes the most profound sleep may be induced, during which teeth may be extracted, and severe operations performed, without the patient being sensible of pain, or having any knowledge of the proceedings of the operator. The process simply consists in causing the patient to inhale the vapour of ether for a short period, and the effect is to produce complete insensibility — or, as the writer says, intoxication. We quote the following case on the same respectable authority: "I took my daughter last week to Martin's [Morton's] rooms to have a tooth extracted. She inhaled the (vapour of) ether about one minute, and fell [fell] asleep instantly in the chair. A molar tooth was then extracted without the slightest movement of a muscle or fibre. In another minute she awoke, smiled, and said the tooth was not out, had felt no pain, nor the slightest knowledge of extraction. It was an entire illusion."

The facts are here so candidly stated that any one may put the new process to the test of experiment. Dr. Morton has made no mystery of his proceedings, like the tribe of hypnotic quacks who have lately perambulated the country. Some caution must, however, be observed in employing the vapour of ether in the way suggested. Ether is a strong narcotic, and its vapour speedily produces complete lethargy and coma, it is exceedingly volatile, and rapidly absorbed and diffused through the body, especially when brought into contact with the extensive surface of the air-cells of the lungs. In one case it has destroyed life, and in another caused apoplexy. Thus an individual may not awaken so readily as the young lady whose case we have here quoted. It must be regarded as producing a state of temporary poisoning in which the nervous system is most powerfully affected, and, as in concussion or narcotic poisoning, sensibility may be so destroyed that operations which in the healthy state would occasion severe pain, may be performed without any consciousness on the part of the patient. The respectability of the source from which we derive our information prevents us from doubting that the writer has accurately described what he saw. The awaking exactly *one minute* after the operation must of course be regarded as an accidental circumstance, depending on the dose of ethereal vapour inhaled. One statement, however, appears to us

*Visiting Professor of Physiology, Yale University School of Medicine.

†A full description of the original communication and the four contemporary reprintings will be found in Fulton and Stanton's *The Centennial of Surgical Anesthesia. An annotated catalogue of books and pamphlets bearing on the early history of surgical anesthesia* (New York: Schuman, 1945).

fore" I also pointed out that, being doctors, they had not previously moved because they could not in honesty move—there were no statistics or actuarial data to warrant the selling of voluntary sickness insurance to the people of the United States with a guarantee that under any kind of sickness a high quality of service would be available.

In 1923 I held a conference all day with the Board of Directors of the Metropolitan Life Insurance Company and tried to persuade them to issue a cheap, voluntary sickness insurance policy on a cash-for-cash basis. But the Board of Directors and a vice-president stated that they could not do so and that they had no statistics on which to figure honestly the risk and the amount that should be paid, as well as no standards of physicians. Today, however, medical standards are on a higher level than those of 1923 and, if organized medicine has anything to say about it, will be kept at that level. Actuarial data are also being accumulated. The large insurance companies are now selling voluntary sickness insurance: the Metropolitan Life Insurance Company has fifteen hundred policies covering 1,700,000 people, and the Equitable Life Insurance Company has twenty-four hundred policies covering 2,800,000 workers in the United States. The policies of all companies represent 23 million workers in the United States who are now covered in whole or in part by various forms of sickness insurance. Few of them get complete coverage for any kind of illness, because the vast majority of American workers do not want such coverage—they want insurance against medical and surgical catastrophe and, sometimes, against obstetrics, which can be a catastrophe.

In addition, the Blue Cross is not what it was twenty-two years ago, it has begun to standardize on a definite level of hospital service and to make use of actuarial data—risks, even those of possible epidemics, are calculated. Twenty-four million people are now insured against hospitalization under the Blue Cross. Under the voluntary sickness plans of many states, the state medical society being the insurer or the controlling influence

and insuring commercially, five and a half million people are covered in the United States. The Council on Medical Service has standardized the plans under the Associated Medical Care Plans, Incorporated, so that a policy will be good from state to state, and will carry the seal of the American Medical Association as an indication that the policy is interchangeable and reaches the quality of service that the Association demands. That is progress.

Progress has also been made broadly through the Veterans Administration, and the medical care of veterans for service-connected disabilities has been extended to many of the states, within another year, most of the states will have organized their programs in such form that a veteran can apply to a doctor of his own choice and be treated in a hospital of his own choice that will meet the requirements of the medical society in the state concerned—all without centralized and federalized control.

Seventy-five million people in the United States carry 40 billion dollars' worth of protection in the form of life insurance that was sold to them by life-insurance agents on a voluntary basis. Yet the sponsors of compulsory sickness insurance tell me that voluntary insurance has never succeeded in any other country in the world—it has always moved into government insurance.

I say that democracy has never succeeded in any other country in the world as it has in our country. And I say, advisedly, that our country is the only country in the world in which democracy still has a chance, because we have the fundamental freedoms for which people fought many years ago: freedom of speech, thought, public assembly and worship, and the right of every man to make of himself the most that he can as an independent American citizen. If we guard those fundamental liberties, I am sure that we can continue to keep medicine in the postwar world on the same high level that it has reached.

THE RECEPTION IN ENGLAND OF HENRY JACOB BIGELOW'S ORIGINAL PAPER ON SURGICAL ANESTHESIA

JOHN F. FULTON, M.D.*

NEW HAVEN, CONNECTICUT

IT IS not widely known that Henry Jacob Bigelow's original announcement concerning surgical anesthesia, which was issued in the *Boston Medical and Surgical Journal* on November 18, 1846, when its author was twenty-eight years of age, was reprinted at least four times within a few weeks of its appearance—twice with the omission of the final controversial paragraphs about the patent and twice in its entirety†

The first reprinting, which included the entire text, appeared in the *Boston Daily Advertiser* on November 19, the day after it had been published in the *Boston Medical and Surgical Journal*. Eager to convey news of the great discovery to his friend Francis Boott, of London, Professor Jacob Bigelow, young Bigelow's eminent father, wrote a letter to him on November 28, in order to get it on the first boat sailing for Europe (December 1), and enclosed a copy of the *Advertiser* for the 19th. The text of this letter, which was published in the January 2, 1847, issue of the *Lancet*, has not often been reprinted and may therefore be of interest

Boston, Nov. 28, 1846

My dear Boott, — I send you an account of a new anodyne process lately introduced here, which promises to be one of the important discoveries of the present age. It has rendered many patients insensible to pain during surgical operations, and other causes of suffering. Limbs and breasts have been amputated, arteries tied, tumours extirpated, and many hundreds of teeth extracted, without any consciousness of the least pain on the part of the patient.

The inventor is Dr. Morton, a dentist of this city, and the process consists of the inhalation of the vapour of ether to the point of intoxication. I send you the *Boston Daily Advertiser*, which contains an article written by my son Henry, and which is extracted from a medical journal, relating to the discovery.

Let me give you an example. I took my daughter Mary, last week, to Dr. Morton's rooms, to have a tooth extracted. She inhaled the ether about one minute, and fell asleep instantly in the chair. A molar tooth was then extracted, without the slightest movement of a muscle or fibre. In another minute she awoke, smiled, said the tooth was not out, had felt no pain, nor had the slightest knowledge of the extraction. It was an entire illusion.

The newspaper will give you the details up to its date, since which other operations have been performed with uniform success.

Several authors have stated that Henry Jacob Bigelow himself went abroad in December, 1846, to bear tidings of the ether discovery, but contemporary references to him in the *Boston Medical and Surgical Journal* indicate that he was definitely in

Boston during December, many also have erroneously attributed to him rather than to his father the letter addressed to Francis Boott.

On what day Jacob Bigelow's letter actually reached London is not known, but the crossing must have been, for those days, extraordinarily quick since the first reference in the British press to the use of ether appeared in the December 18 issue of the *London Medical Gazette*. This suggests that the vessel sailing on December 1 must have arrived in England at least by December 16, for two days gives small margin for delivering the letter,—which probably arrived at Liverpool,—abstracting its contents and setting it up in type. Since the text of this first announcement has not been alluded to in recent histories on anesthesia, it is given here.

ANIMAL MAGNETISM SUPERSEDED — DISCOVERY OF A NEW HYPNOSIS

We learn on the authority of a highly respectable physician of Boston, U. S., that a Dr. Morton, a surgeon-dentist of that city, has discovered a process whereby in a few minutes the most profound sleep may be induced, during which teeth may be extracted, and severe operations performed, without the patient being sensible of pain, or having any knowledge of the proceedings of the operator. The process simply consists in causing the patient to inhale the vapour of ether for a short period, and the effect is to produce complete insensibility—or, as the writer says, intoxication. We quote the following case on the same respectable authority: "I took my daughter last week to Martin's [Morton's] rooms to have a tooth extracted. She inhaled the (vapour of) ether about one minute, and fell [fell] asleep instantly in the chair. A molar tooth was then extracted without the slightest movement of a muscle or fibre. In another minute she awoke, smiled, and said the tooth was not out, had felt no pain, nor the slightest knowledge of extraction. It was an entire illusion."

The facts are here so candidly stated that any one may put the new process to the test of experiment. Dr. Morton has made no mystery of his proceedings, like the tribe of hypnotic quacks who have lately perambulated the country. Some caution must, however, be observed in employing the vapour of ether in the way suggested. Ether is a strong narcotic, and its vapour speedily produces complete lethargy and coma; it is exceedingly volatile, and rapidly absorbed and diffused through the body, especially when brought into contact with the extensive surface of the air-cells of the lungs. In one case it has destroyed life, and in another caused apoplexy. Thus an individual may not awaken so readily as the young lady whose case we have here quoted. It must be regarded as producing a state of temporary poisoning in which the nervous system is most powerfully affected, and, as in concussion or narcotic poisoning, sensibility may be so destroyed that operations which in the healthy state would occasion severe pain, may be performed without any consciousness on the part of the patient. The respectability of the source from which we derive our information prevents us from doubting that the writer has accurately described what he saw. The awaking exactly one minute after the operation must of course be regarded as an accidental circumstance, depending on the dose of ethereal vapour inhaled. One statement, however, appears to us

*Starting Professor of Physiology Yale University School of Medicine

†A full description of the original communication and the four contemporary reprintings will be found in Fulton and Stanton's *The Craniology of Surgical Anesthesia. An annotated catalogue of books and pamphlets bearing on the early history of surgical anesthesia* (New York: Schuman, 1946).

to require explanation. We can understand the production of insensibility and the temporary loss of consciousness from the effects of ether, but we do not comprehend how, when the individual was perfectly roused to consciousness, there could be the slightest doubt as to whether the tooth was in or out of the mouth! All who have undergone this operation know that from the imperfect sense of touch possessed by the tongue, that the gap occasioned by the loss of a tooth appears about ten times as large as it really is. Then, again, we can believe that no pain might be felt during the operation, but how can any narcotic annihilate pain *in futuro*, when its effects on the nervous system have entirely ceased? Ordinary sleep often produces a temporary loss of sensation of pain but this immediately returns in the waking state.

This announcement has a footnote appended reading as follows: "We have since learned from another quarter that the respiration of the vapour has been tried in numerous cases without occurrence of any accidents." This suggests that the editor of the *Gazette* had at first seen only the Jacob Bigelow letter and was subsequently shown the communication that appeared in the *Boston Daily Advertiser*.

The story of Boott's transmission of the Bigelow letter and the *Daily Advertiser* reprint to Robert Liston is well known, but the speed with which Liston verified the discovery has not been sufficiently emphasized. It appears that Liston was informed of Bigelow's paper some time on Friday, December 18, the day on which the *Gazette* appeared, on Saturday he obtained some ether, and on Sunday he worked all day trying to perfect an inhaler, which he tried out on his nephew William Squire*. On Monday, December 21, he carried out his celebrated amputation at the thigh—the first operation under ether anesthesia to be performed outside the United States. A few hours after the operation had been completed, Liston wrote Boott: "I tried the ether inhalation today in a case of amputation of the thigh and in another requiring evulsion of both sides of the great toenail, one of the most painful operations in surgery, and with the most perfect and satisfactory results." This Liston letter and the correspondence between Jacob Bigelow and Francis Boott and between Boott and Liston were all published in the issue of the *Lancet* previously mentioned, likewise reprinted was the full text of Henry Jacob Bigelow's communication

in the *Boston Medical and Surgical Journal*, as reprinted in the *Advertiser*.

On the editorial page of this number of the *Lancet* there is the following brief, but significant, comment:

In another page we insert an important communication kindly forwarded to us by Dr. Boott, of Gower Street, describing the important discovery of an apparently harmless means of producing insensibility during the performance of surgical operations. The means of performing operations without pain has, in all ages, occupied the attention of the profession. The realization of such an object, by means so simple as the inhalation of the vapour of sulphuric ether, cannot but redound to the great merit and reputation of the discoverer, Dr. Morton, of Boston, America; and to the honour of the profession to which he belongs. It is almost impossible to discredit the statement contained in the communication referred to, from which it will be seen that a great number of operations, from the extraction of teeth to the gravest operations of surgery, have been painlessly performed. This discovery seems to have a remarkable perfection about it, even in its first promulgation. We shall watch its development in the various branches of medicine and surgery which may admit of its application, and carefully record them. We suppose we shall now hear no more of mesmerism and its absurdities as preparatives for surgical operations. The destruction of one limb of the mesmeric quackery will be one not inconsiderable merit of this most valuable discovery. The operations of Mr. Liston, at University College Hospital, were performed after the inhalation of ether, by means of an apparatus contrived by Mr. Squires of Oxford Street. It appears, from a communication in another column, that the discovery has been patented for Great Britain and the Colonies.

The growth of interest in ether anesthesia in other countries was almost phenomenal for those days of slow communication, indeed, knowledge of anesthesia spread more rapidly on the continent of Europe† than it did in the United States, where the introduction of this new surgical concept was actively resisted in many centers, including New York, New Orleans and, particularly, Philadelphia. It is amusing, in retrospect, to find that that stately sheet the *American Journal of Medical Sciences*, so long edited in Philadelphia, refused throughout the year 1847 to publish a single original communication on anesthesia, although it did include, probably with reluctance, a few brief abstracts on the use of ether. The conservative *Lancet*, on the other hand, published nearly two hundred letters, communications, and editorials during 1847. An even larger number appeared during that year in the *Boston Medical and Surgical Journal*, and its successor, the *New England Journal of Medicine*, can now point with justifiable pride to having carried, one hundred years ago, the announcement of the greatest single discovery in the history of modern medicine.

†Accounts of the introduction of anesthesia in various countries of the world will be found in the "Anesthesia Number" of the *Journal of the History of Medicine and the Allied Sciences* (October 1946) and in the anesthesia numbers of the *British Medical Bulletin* (July 1946) and the *British Medical Journal* (Oct. 12, 1946). Attention must be directed, finally, to the new definitive history of inhalation anesthesia by Dr. Barbara Duncan (*The Development of Inhalation Anesthesia, with Special Reference to the Years 1846-1900*) just published for the Wellcome Historical Medical Museum in London.

FUNCTIONAL GASTROINTESTINAL DISORDERS LESSONS LEARNED FROM MILITARY MEDICINE*

JAMES A. HALSTED, M.D.†

BOSTON

IT HAS long been customary to treat functional gastrointestinal disorders by means of smooth diets, antispasmodics, sedatives and rest. Hospitalization is sometimes recommended in severe cases. Experience in the management of soldiers with these disorders demonstrated that this type of treatment was not only unsuccessful in relieving symptoms but also harmful from a military point of view because it rendered the men unnecessarily ineffective as soldiers. The reason for this was that at least 80 per cent of the cases were psychogenic. Dealing with the personality disturbance directly and promptly, with a minimum of emphasis on medical study and organic therapy, resulted in a significant saving in manpower, a marked decrease in hospitalization and benefit to the patients. It is believed that the lessons learned in the study of soldiers with functional gastrointestinal disorders may be applied to the treatment of these conditions among civilian patients.

GENERAL CONSIDERATIONS

Functional gastrointestinal disorders accounted for a large part of disability from medical causes in the United States Army. The chief manifestation was epigastric distress or dyspepsia. In the British Army dyspepsia was, according to Hurst et al.,¹ the largest single type of disease. Regarding the incidence of peptic ulcer in relation to all cases of dyspepsia it is difficult to evaluate statistics, which are always conditioned by the type of hospital from which they are gathered. A study of the available sources of information indicated, however, that the incidence of ulcer among American troops was no greater than that in civilian life. Combat did not cause new ulcers to develop — less than 4 per cent of 183 consecutive patients with chronic epigastric distress in the Fifth Army who were completely studied were found to have peptic ulcer.²

Careful study of ulcer and nonulcer dyspepsia was made at the Sixth General Hospital in Casablanca and in a gastrointestinal center of the Fifth Army.³ Although the digestive symptoms of about a quarter of the patients with nonulcer dyspepsia superficially resembled those of ulcer, the personality types were nearly always totally unlike. This difference was so constant that a diagnosis could be made from the history alone with an accuracy of about 90 per cent. Psychiatric study of 100 patients in each group revealed that 80 per cent

of the nonulcer patients were psychoneurotic in the sense that they were rendered ineffective by neurotic symptoms in addition to the dyspepsia. In the ulcer group only 6 per cent had disability resulting from psychoneurosis. The personality make-up of the ulcer patient was that of a restless, ambitious person intensely anxious to succeed and to prove himself a leader. He was self-sufficient, self-reliant and usually an excellent soldier; he did not, characteristically, make use of his symptoms to get out of unpleasant situations — on the contrary, he often concealed his symptoms. The patient with functional dyspepsia, on the other hand, was generally an habitué of sick call, and typically was a submissive, passive person. Two fifths of these patients came from broken homes, and about half had a history of neurotic traits and phobias.

The clinical picture in the two groups was as a rule entirely different. In the functional group the main symptom was diffuse epigastric distress occurring while eating or immediately thereafter. Vomiting was frequent but usually consisted in regurgitation of a small amount of food after eating. Loss of weight was not evident. These patients, who rarely had diarrhea or large-bowel symptoms, nearly always complained of other symptoms, such as insomnia, lightheadedness, fatigue and headache. The patients often had lifelong dislike of certain foods, being extremely fussy about what they were able to eat. They were convinced that their symptoms were caused by the wrong food, but they rarely felt any better when given a bland diet in the hospital.

In contrast, the ulcer patient was nearly always relieved of symptoms as soon as he was hospitalized, even when good dietary facilities were not available. The symptoms were typical of ulcer, with a food-pain-food-relief sequence in 72 per cent of the cases. Vomiting was rare, and the patient generally complained of nothing more than localized epigastric pain. Characteristically, he did not complain about this unless asked.

The strikingly prompt relief of symptoms with hospitalization in ulcer patients seen overseas was attributed largely to relief of nervous tension, because in each case the soldier knew he was to be sent home with an acceptable organic disease, having done his job. Although nervous influences peculiar to Army life overseas did not result in an increased incidence of new ulcers, old ulcers were reactivated or intensified by nervous tension.² The subsidence of symptoms coincident with relief of nervous tension can be likened to that following vagotomy, when pain is likewise promptly relieved.

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 21, 1946.

†Assistant in medicine, Harvard Medical School, physician-in-chief, Faulkner Hospital.

In the former, hypersecretion and hypermotility are arrested, perhaps from cessation of vagal overstimulation by reducing psychic tension, and in the latter by surgical interruption of the vagal pathways from the higher centers to the stomach.

The proportion of ulcer patients with psychoneurotic symptoms is probably considerably higher in civilian practice than that in the Army overseas, because the overseas group was a highly selective one, neurotic patients with ulcer being much likelier to get themselves out of the Army than the aggressive ambitious type to which most of the overseas ulcer patients conformed. As a result of this selective process, it was much less frequent to find an association of neurosis with chronic organic disease in the Army overseas than in civilian practice. Thus, differential diagnosis was of great positive and practical value in estimating the personality of the patient.

At the Sixth General Hospital in Casablanca, a base hospital that was far back from the Tunisian front, the patients with functional dyspepsia had generally been in other medical installations for several weeks before they were received. When symptoms were vague or persistent and did not respond to treatment at forward hospitals, the patients were evacuated to the rear for investigation. When the symptoms were actually part of a psychoneurosis, hospitalization and repeated medical investigation rendered these patients less and less effective—62 per cent had to be returned to the United States, and a large proportion of those returned to duty were soon rehospitalized. An attitude on the part of the examining physician that led to exclusion of organic disease by all possible diagnostic tests before a neurotic etiology was accepted, even if there was positive evidence of neurosis, caused fixation of symptoms and magnification of the illness in the patient's mind. The patient with a psychosomatic syndrome, like every soldier, was in a conflict between duty and self-preservation. A prolonged search for organic disease apparently resulted in intensification of the neurosis by which the psychosomatic patient was solving this conflict.

Although prolonged investigation was harmful to patients with functional dyspepsia, it was not the investigative procedure itself that was harmful but the way in which it was carried out. Thus, if the history was taken only from the viewpoint of the gastric symptomatology and followed by x-ray and laboratory studies, with eventual evacuation of the patient to a rear hospital for further examination because the symptoms had not been relieved by treatment and because no physical cause had been found, the patient's mind was conditioned to organic disease, largely because the physician had manifested doubt regarding the diagnosis to the patient. When a decision was finally made in the rear hospital to return the patient to duty, it was

quite natural for him to feel resentful and to believe that the proper diagnosis must have been missed.

It seemed clear that if such patients could be evaluated promptly close to the front, a considerable saving in manpower would result. In 1943 in Italy, such an opportunity was provided by the establishment of a gastrointestinal center in the Fifth Army, at which all types of gastrointestinal disease were seen but the main diagnostic problem was the differentiation of ulcer and nonulcer dyspepsia. The patients were interviewed at length and a psychiatrist examined those in whom there was doubt concerning the diagnosis. If the symptoms were believed to be psychogenic, the patient was so informed. X-ray facilities were not at times adequate, although in doubtful cases x-ray examination could be done. As a result of complete studies previously carried out in a similar group of patients at the base hospital, it was believed the ulcer could be eliminated from the history with a high degree of accuracy. When the study of the patient was completed, a decision whether or not he was fit for further duty was made chiefly on the basis of psychiatric factors. He was then again interviewed, and the mechanism of symptoms, as well as the decision regarding his disposition, was explained to him. Treatment of the stomach symptoms by means of rest, diet and medicine, which was invariably fruitless, was not attempted, since in itself such treatment was unsettling to the neurotic patient. The symptoms, being a manifestation of anxiety and personality disturbance, could not be cured by medicine. Although malingering was rare, there was usually an unconscious exaggeration of symptoms.

As a result of this method of management, the patients felt confidence from having been taken seriously and having been well examined. Under these circumstances, they returned to duty quite willingly, for they still retained their sense of unit morale, not having been separated from their unit for more than a week.

The results of this system were militarily beneficial. 80 per cent of patients with functional dyspepsia were returned to combat duty, and about 10 per cent were reclassified for noncombat duties in other organizations, in about 10 per cent of cases either the patients were too sick psychiatrically for any type of duty or there was sufficient doubt regarding the diagnosis to warrant evacuation to a rear hospital. A follow-up study of those returned to duty two to four months later demonstrated that 83 per cent were still on duty and that 68 per cent of these were considered effective as soldiers by their officers. The contrast between these figures and the results obtained when the patients were hospitalized for long periods, as at Casablanca, is striking. Even though the neuroses of patients in the Casablanca group were severer than those in the Fifth Army group, there was no

doubt that unnecessarily prolonged medical investigation played a major role in the unsatisfactory results. Although the Fifth Army patients were all combat soldiers, the symptoms were not merely a reaction to combat, since 68 per cent had had symptoms in civilian life. The system of early and prompt treatment and disposition was beneficial to the patient individually, by preventing perpetuation of symptoms. It was therefore sound preventive medicine.

The Army setting was an artificial one in comparison with civilian practice in that neurotic patients with a chronic organic disease were apt to be screened out before they were sent overseas. Furthermore, the patients were all young men living under nearly identical conditions. It provided an experimental situation, however, in which observations could be made more precisely than in civilian clinics. Thus, the effect of nervous influences associated with combat could be studied in relation to peptic ulcer, and the adverse effect of ill-advised medical investigation on psychosomatic conditions could be demonstrated with precision. It is now necessary to determine whether these observations can be applied to the treatment of functional gastrointestinal disorders in civilian practice.

The clinical picture differed in the Army from that seen in civilian practice. Dyspepsia and epigastric symptoms predominated, patients with large-bowel symptoms of colicky pain, constipation and intermittent diarrhea being quite rare. In World War I neurocirculatory asthenia, or soldier's heart, was the major psychosomatic syndrome. Although that symptom was not infrequent in World War II, dyspepsia, or "soldier's stomach," as it has been termed, seems to have taken its place as the main psychosomatic disorder. The symptomatology, outlined above, was so uniform that it seemed at times to assume epidemic proportions. The factor of suggestibility in neurotic patients may have been the reason for the uniformity in symptomatology.

In civilian practice patients with functional disorders seem to have much more varied symptomatology, large-bowel syndromes predominating. Furthermore, the majority of patients are women, and they are in older age groups. The fundamental etiologic factors, however, are apparently the same.

ETIOLOGY

There are four main explanations for a functional gastrointestinal disorder. It may be associated primarily with an organic disease, such as tuberculosis or nephritis or with the menopause. It may occur in a perfectly normal person subjected to unusual physical or emotional strain — in such cases it is temporary, being relieved when the external circumstances causing the strain are corrected, and is essentially physiologic. It may occur in emotionally stable

persons who seem to have a low threshold for gastrointestinal symptoms that are precipitated by external influences that do not affect the average person, mild fatigue, normal fear, nicotine, alcohol, certain foods and irregular eating habits are examples of such influences. Finally, the disorder may be part of an emotional disturbance or neurosis, often masking other symptoms of the neurosis so that on superficial examination dyspepsia, pain, heartburn, vomiting and so forth seem to be the only difficulties.

The physiologic mechanism responsible for symptoms is not completely understood, but disturbance in motility appears to be the essential feature. Measurement of gastric secretion is without value in assessing the etiology of symptoms, since the same symptoms may occur whether or not hyperacidity, anacidity or normal acid values are present. Changes in vascularity probably play a secondary role in the production of gastric symptoms. Wolf and Wolff⁴ demonstrated that stimulation of the normal gastric mucosa resulted in no sensations but that when the mucosa was turgid and edematous the same stimulation produced symptoms. In connection with motor phenomena, a word should be said about pylorospasm, which has long been considered the origin of symptoms in many cases of dyspepsia, often being said to be a pathologic entity. Evidence for pylorospasm is by inference, being based chiefly on roentgenography when the pylorus fails to open to allow barium to pass through. Recent studies suggest that there is no such thing as pylorospasm, except in ulcer or adjacent inflammatory disease.⁵ The failure of the pylorus to open may be due not to spasm but to absence of peristaltic contractions sufficiently strong to cause it to open. Spasm may occur in the body of the stomach, however, being frequently observed at gastroscopy. In gastroscopy of 110 soldiers with nonulcer dyspepsia spasm was noted in the mid-body region of the stomach in 7 cases.⁶ In 2 of these cases the patients stated that an exact reproduction of their usual symptoms took place at the time the spasm was noted. The gastric mucosa was normal in both cases.

TREATMENT

Regarding treatment, it is first necessary to determine which of the four fundamental causes of the disorder is the basis of symptoms in the patient. If the disorder is primarily associated with external factors, such as overwork, improper food and overindulgence in tobacco, the approach to the problem is essentially an organic one — that is, the emphasis is on rest, diet and drugs. On the other hand, if emotional tension or psychoneurosis is the basic difficulty, the treatment should be primarily psychiatric. Bed rest, diet and drugs in the treatment of neurosis, unless used merely as temporary adjuncts to psychotherapy, are harmful because

they tend to perpetuate the neurosis, making subsequent psychotherapy more difficult. Menninger⁷ has pointed out the reasons why neurotic patients uniformly demand physical treatments and resist facing underlying emotional factors: they always prefer to have a physical rather than a mental illness, and physical treatment justifies the patient's desire and belief that he should be considered physically ill. Bennett⁸ has made a study of 150 patients on the medical and surgical wards of a general hospital whose complaints were eventually diagnosed as psychoneurosis. A large proportion had gastrointestinal symptoms, four hundred and ninety-six courses of medical and two hundred and forty-four courses of surgical treatment had previously been conducted, never with more than temporary benefit. Such fruitless therapy involves enormous waste of time and money and tends to encourage reliance on cults, with loss of confidence in the profession.

The treatment of functional gastrointestinal disorders in soldiers was in a sense a negative one. The patient could only be told what the trouble was and that he would have to live with it. The environment could not be altered, nor could sources of frustration, resentment or anxiety be eliminated. Delving deeply into the background of the patient in an attempt to alter basic difficulties was unsuccessful and unwise—one patient in whom this was attempted developed marked mental anxiety, and another developed hysterical paralysis of a limb. In civilian practice external factors can be altered. Compromises, adjustments and a changed viewpoint can be effected. Because there is a greater incentive to get well, simple psychotherapy may be successful, especially if carried out early before harmful measures that strengthen the neurosis have been applied.

In functional illness the process of making the diagnosis is in itself an effective therapeutic measure. Even though the physician is sure after five minutes' conversation that the disorder is functional it is imperative that a thorough history be taken, a thorough examination made and essential laboratory and x-ray studies carried out. It is important, however, that these investigations be performed but once and that after this systematic examination is made the physician speak with conviction and positiveness. The most valuable part of the examination is the history, which may disclose positive evidence of emotional instability. Such a positive finding is as essential to the diagnosis of a psychogenic disorder as x-ray evidence is to the diagnosis of peptic ulcer. It must not be a diagnosis of exclusion. The physician need not have psychiatric training to recognize emotional factors, but he should have the experience to appreciate that they may produce major physical discomfort. If one embarks on an unreasonably prolonged search for organic disease or picks an incidental finding, such

as a spastic colon, treating the patient as if that were in itself a disease entity, the patient will become convinced that he is organically ill. Such treatment, however, often results in temporary symptomatic relief at least during the time that the patient is under the physician's care, in contrast to soldier patients, in whom it was rarely beneficial.

In functional gastrointestinal disorders caused by distant organic disease or by external strains in a normal person, the treatment is obviously that of removing the causes. In those due to external strains in a patient with a low threshold for gastrointestinal symptoms, the patient must be taught his limitations and how to adjust his life to them. Antispasmodics, a simple diet and adequate rest are of considerable help.

It is in the group with psychogenic symptoms that therapy is the most difficult. Since this comprised four fifths of the soldier patients, it is reasonable to suppose that it is the largest group in civilian practice. The greatest obstacle is the factor of time. Most physicians do not have enough time to deal thoroughly with a psychogenic disorder. It is difficult to persuade patients with a psychosomatic syndrome to consult a psychiatrist, for the essence of this type of disorder is the patient's resistance to accepting the fact that the symptoms are emotional in origin. A trap is therefore set by which symptoms may become fixed. The patient wants organic therapy, and owing to the physician's lack of time, it is easier to give it than to spend a few hours dealing with the patient's problems.

If psychogenic gastrointestinal disorders were correctly diagnosed and properly treated at the beginning, much subsequent disability and invalidism could undoubtedly be prevented. In the first stages simple measures are often successful without the expenditure of a great deal of time.

In brief, the first step is to explain clearly that although the symptoms are not caused by any physical abnormality, they are real. Nearly always the patient fears that the doctor considers the symptoms imaginary. A physiologic explanation of symptoms is helpful, with a description of how exaggerated nerve impulses resulting from tension or anxiety travel to the intestinal tract and cause spasm, which produces distress. Often the patient asks whether these abnormal conditions may lead to cancer or ulcer, and reassurance is necessary on this point alone. Reassurance that the patient has nothing seriously wrong, however, is in itself of little value. A positive statement by the physician that the patient will feel better and that he can get well often has a marked therapeutic effect. If this has been preceded by a thorough clinical examination, it may be one of the most potent forces in therapy. Explanation, reassurance and suggestion by themselves are generally not enough and should be reinforced by the support of the physician, who

must give the patient advice how to adjust himself to difficult situations and try to make the patient see how situations that produce nervous strain are often followed by symptoms. The tendency of the patient is to say that nervousness is caused by the symptoms. If the patient can be made to understand that emotional difficulties are actually causing them, he will be a long way on the road to solving these difficulties himself.

In purely psychogenic disorders a bland diet, antispasmodic drugs and mild sedation with phenobarbital all have a place. Doubtless these agents at times have both a physiologic and a pharmacologic action, but it may be seriously questioned whether the beneficial results attributed are not usually those of suggestion — a symbol of the doctor's authority. Certainly the patient will welcome such treatment, and in some cases it may be given at the start. The patient should be told emphatically, however, that this is given only for the secondary manifestations and will not affect the cause of his difficulty. Because the patient frequently improves, it is a temptation to continue a medical regime indefinitely. This practice is basically unsound, being harmful by creating the belief that the symptoms are of physical origin.

Of course, in a great many patients who are confirmed gastrointestinal invalids, simple common-sense psychotherapy is of no avail. These patients demand diet ceremonials, vitamins and other medicines and resist any attempts to explain their symptoms on an emotional basis. Few accept the suggestion that they see a psychiatrist, and it is indeed probable that expert psychotherapy would not cure many patients in whom the symptoms are firmly fixed. It seems likely that much of this invalidism is largely caused by injudicious medical therapy at the beginning and that a better understanding of functional illness, with treatment of

basic causes rather than the organ involved, can prevent much future disability.

SUMMARY

Men with functional gastrointestinal disorders formed one of the largest single groups of medical patients in the Army Hospitalization, with prolonged investigation and medical treatment, had an adverse effect because the great majority of the disorders were psychogenic. Prompt evaluation, with early discharge from medical channels, resulted in military benefit by preventing perpetuation of symptoms.

The personality of soldiers with peptic ulcer seen overseas differed markedly from that of patients with nonulcer dyspepsia. This observation was useful in differential diagnosis, being of practical value in forward areas, where x-ray facilities were not always available.

In civilian patients with psychogenic gastrointestinal disorders, treatment with diets, drugs and other forms of organic therapy, unless used as a temporary adjunct to psychotherapy, may be a major cause of disability and invalidism by fixation of symptoms.

MEDICAL ASPECTS OF HYPERTENSION*

NORMAN A. WELCH, M.D.†

BOSTON

HYPERTENSION, with its allied circulatory disorders, is probably the most frequent single abnormal medical condition seen in practice. There are believed to be about 15,000,000 people in the United States with some degree of hypertension. These cases are usually divided into those in which the hypertension is a manifestation of some specific disturbance of the body, such as nephritis or hyperthyroidism, and those in which it is the sole abnormal finding on examination, or in which other findings existent at a particular time are presumed to have been secondary to an earlier essential hypertension. In a discussion of this sort it seems feasible to ignore cases in which the abnormally high pressure is secondary to other diseases because the main consideration in such cases is the investigation and treatment of the primary disorder.

Essential hypertension has long been an enigma to the clinician, and vast amounts of energy and money have been expended in a search for the causative factors, that more effective preventive and therapeutic measures might be developed. The work of Goldblatt¹ on the effect of renal ischemia on blood pressure served to focus attention on the results of slowing down the circulation to one kidney. One practical effect of the publication of this material has been our routine search for unilateral kidney lesions as a cause for hypertension. At times, spectacular remissions have occurred with correction of such a remedial condition as a unilateral congenital poorly functioning kidney.

Subsequently, the work of Page and his associates²⁻⁶ indicated that the kidney liberates into the blood stream a proteolytic enzyme (renin) that acts on a blood globulin to produce a polypeptid with a pressor effect — angiotonin, or hypertensin. Experimental renal ischemia has been reported as producing an increase in circulating renin and angiotonin,⁷⁻¹⁰ and the same results are said to occur in eclampsia and severe glomerulonephritis.¹¹ The assumption, however, that a deficient renal circulation produces essential hypertension by the increased elaboration of renin and angiotonin was upset by the demonstration that renin is not found in the blood in essential hypertension,¹² although it is present in renal hypertension and severe glomerulonephritis. Nor is there any increase in the globulin precursor of angiotonin in essential hypertension.¹³

A further accumulation of doubt regarding the role of a humoral pressor mechanism arose with the demonstration that repeated transfusions from

hypertensive subjects did not cause blood-pressure elevation in the recipients.¹⁴ It was also demonstrated by several investigators that renal blood flow in essential hypertension is normal,¹⁵⁻¹⁸ so that there appears to be no evidence of renal ischemia in the genesis of this condition. It may be said that the excellent work of Goldblatt has resulted in a tremendous amount of clinical investigation, some of the results of which were aptly expressed by Smith and his co-workers¹⁹ as follows: "So far as the genesis of essential hypertension is concerned, the kidney appears to be the victim rather than the culprit." Page's^{20, 21} confirmation of this statement is borne out by his conclusion that there is little evidence that persistent reduction of blood flow and oxygen utilization occurs within the kidneys except when hypertension is of long duration and severe secondary vascular change has supervened.

Circulatory interference with other tissues has been advanced as a cause of arterial hypertension. The recent and as yet unfinished investigation of Victor and his associates²² revealed a marked, persistent increase in blood pressure in six dogs in which ligation of the left adrenal vessels was carried out. A theory that hypertension is caused by excitation of the vasomotor center as a result of the ischemia associated with arteriosclerotic changes in the small vessels of the medulla²³ does not seem to have been borne out by the pathological findings of others, including Cutler.²⁴

The neurogenic theories of hypertension are rapidly replacing those having to do with a renal etiology. The reactions of the vasomotor center are influenced by such factors as carotid-sinus reflexes, oxygen and carbon dioxide tension, medullary circulation and certainly by nervous and emotional states. According to Donnison²⁵ and Williams²⁶ hypertension is rare in the African Negro but is frequently seen in the Negro in metropolitan areas of the United States.^{27, 28} The influence of psychosomatic factors in elevated blood pressure has been mentioned by a number of authors.²⁹⁻³³ Everyone who has had occasion to treat hypertension has noted the result of psychogenic influences on some patients. The effect of inhibited, excessive, competitive and hostile reactions on the blood pressure is well known to every physician. Similarly, the favorable response incident to the control or elimination of such hypertensive stimuli is common knowledge. The persistent occurrence of such mental states and the knowledge of the beneficial effects obtained by their proper handling have led to the frequent usage of various sedatives. The continuation of this therapy is assured by an

†Clinical professor of medicine, Tufts College Medical School; physician-in-chief, Carney Hospital.

increased observation of the neurogenic factor in hypertension, and by a firm belief that sustained vasomotor stimulation caused by such nervous and emotional influences eventually leads to fixed hypertension—an assumption that is lent great weight by the report of Levy, Hillman, Stroud and White³⁴ on the occurrence of transient hypertension in a large group of United States Army officers. They found evidence that at all ages, sustained hypertension developed oftener in persons who had previously shown transient hypertension than in those who had not.

Many years ago, Dr. James P. O'Hare pointed out to me that the early stage of essential hypertension may be characterized by intermittent elevations of pressure followed by remissions to normal. He also concluded, after long observation of a large number of hypertensive patients in the clinic and in private practice, that a certain number are not particularly troubled by essential hypertension, living through what appears to be for them a normal span of years and then dying of some extravascular disorder. Recently, concentration on the neurogenic element in hypertension has resulted in recourse to surgical therapy in some cases. It is to be hoped that the pendulum will not swing too far in that direction, and yet there is some suggestion that it has already done so. The recommendation sometimes made that young persons in the early intermittent or transient stage of hypertension be subjected to surgery hardly seems justified in view of the knowledge of the normal life expectancy of a certain percentage of such a group. Peet and Isberg³⁵ have pointed out that the acceptance of surgical treatment has been tempered with the realization that its limitations are definite and that failures are not infrequent. No one can review such a report without recognizing the distinct value of the surgical procedure that is advocated in certain selected cases. That there is difficulty in choosing the ideal case for surgery is readily admitted, but I believe that rapid strides are being made toward the solution of this troublesome problem.

Various procedures have been used to determine the lability of the blood pressure in a particular case and in this way to set up criteria for the selection of suitable operative cases. The proper determination of operability is of great importance to the internist, who is often the one to make the surgical recommendation. If the results of such therapy are universally poor, a valuable procedure may fall into disrepute and may thus deprive some patients of increased comfort and prolonged life. The sodium amytal, sodium nitrite and cold-pressor tests are still used routinely as part of the investigation into the degree of neurogenesis in essential hypertension. The failure of these tests accurately to prophesy success for sympathectomy in some cases indicates the need for a more effective evaluating mechanism.

The recently published studies of Russek, Southworth and Zohman³⁶ on the use of continuous caudal anesthesia as a means of selecting hypertensive patients for surgery suggests that this procedure offers a valuable indication of the success or failure of sympathectomy. Unfortunately, there is no evidence regarding how long these patients were followed postoperatively. The assumption that it may be possible to correlate the level of anesthesia necessary for a satisfactory fall in blood pressure with the extent of surgery required for relief is certainly interesting and indicates the progress that may well be made in arriving at a proper surgical evaluation.

It is worth remembering that in many cases in which surgery has failed to alter the blood-pressure reading materially, a favorable influence has been exerted on distressing symptoms. In the series reported by Bartels, Poppen and Richards³⁷ 71 per cent of patients received symptomatic relief, although half continued with an elevated pressure. Similar results are frequent in other case series. It hardly seems justifiable at present, however, to recommend such a serious surgical procedure purely for the temporary relief of symptoms.

The classification of patients according to fundoscopic changes and alteration of cardiac and renal function is certainly most desirable as a means of measuring the progress of a vascular disease. An adequate period of careful observation may well result in presenting to the surgeon at a more favorable time the occasional case in which sympathectomy will be beneficial.

From the standpoint of the internist and the general practitioner it is obvious that the most useful type of treatment is that afforded by psychotherapy, particularly in the form of reassurance, and by the time-honored use of sedatives that offer additional reassurance by lessening nervous tension and promoting sleep. Far too many people in this section of the country are blood-pressure conscious, and yet such a state of mind is beneficial from the standpoint of preventive medicine because it enables the physician to steer these people along a better nervous and emotional course. In this way he is able to remove early some of the vasospastic element that might conceivably contribute to vascular change and a speeding of the patient along the road to permanent fixed hypertension.

I remember two young women who were strongly urged to subject themselves to sympathectomy because of transient hypertension, obviously related to sleeplessness and worry. Neither has shown an elevation in the blood pressure for some time, one having gone four and a half years without symptoms and with a blood pressure of 136 systolic, 90 diastolic, as compared with an original reading of 162 systolic, 100 diastolic. The only therapy has been reassurance and limited sedation.

I am still of the opinion that iodides are valuable in the treatment of vascular diseases, including

hypertension. Similarly, the nitrites are useful in some cases because of their antagonistic effect on vasospasm. O'Hare et al.^{38, 39} have shown the dramatic effect of thiocyanate therapy in selected cases of hypertension in which the dosage was carefully regulated by determination of the blood cyanate levels. A few years ago there was high hope for the commercial development of a renal extract with an antipressor effect, but such a product has not yet been assured.

* * *

In conclusion, I should like to make a sincere plea that the fundamental treatment of essential hypertension be continued on a conservative basis, and that these patients be given every advantage of study over a reasonable period, so that the progressive or regressive character of their conditions may be accurately determined. This approach to an important problem will undoubtedly assure many of these patients a normal life expectancy, and will place in the hands of the surgeon at a more opportune time patients who will probably be benefited more specifically by sympathectomy.

MEDICAL PROGRESS

BIOCHEMICAL ABNORMALITIES DURING RENAL INSUFFICIENCY*

STANLEY E BRADLEY, M.D†

BOSTON

DURING recent years the theory of metabolism has undergone an extensive revision as a result of the work of Borsook and Keighley,¹ Tarver and Schmidt,² Schoenheimer³ and others. This new point of view, summarized by Schoenheimer, has had a profound influence on thinking in biochemistry and physiology. In particular, it has been necessary to reassess the part played by the kidney in the body economy and to reconsider — in terms of the organism as a whole — the biochemical abnormalities that arise during renal insufficiency.

According to modern theory, the components of the body are in a state of continual change. Thus, the constancy of any biologic structure does not imply stability, but denotes a balance of the processes of degradation and regeneration in which its ingredients participate. Complex molecules of all types break down or lose molecular groups and are again rebuilt or regain lost groups. This intricate and cyclic activity takes place in a circulating so-called "metabolic pool," in which small molecules derived from degradation or digested food are carried throughout the body. Likewise, the mineral constituents of cells and body fluids are in dynamic equilibrium, undergoing continuous movement and exchange.

It is obvious that the position of the kidney in this activity is extremely important, since it governs the composition of the metabolic pool through its regulation of the chemical structure of the plasma, although the factors involved are obscure.⁴ It is equally probable that the kidney acts to maintain the constancy of some single plasma characteristic, such as ionic strength, osmotic pressure, water, base or hormone content or the constancy of several. In any case, the net result is a remarkably small range of variation in the composition of the plasma under diverse conditions. Since the plasma is in equilibrium with the remainder of extracellular fluid, which, in turn, is in equilibrium with intracellular fluid in most respects, it follows that renal activity determines the structure of all body fluids making up the metabolic pool.

Although many biologic processes are, to a large extent, independent of the composition of the metabolic pool, it seems certain that extensive changes, such as those occurring during renal insufficiency,

may disturb chemical reactions everywhere in the body and ultimately lead to fatal dislocation of the metabolic balance. According to this view, it is gratuitous to seek an explanation for the clinical manifestations of uremia in the renal retention of specific toxic waste products. Any great loss of water and electrolytes, with a retention of catabolites by the damaged kidneys, is sufficient to provoke serious disturbances of cellular activity, with resultant clinical phenomena. Thus, a study of the chemical structure of the blood during renal disease reveals not only the effects of renal dysfunction on body fluids, but also the causes of cellular dysfunction elsewhere in the body.

The failure of the renal mechanisms that normally regulate the composition of the blood — that is, renal insufficiency — arises from a wide variety of disorders and produces an equally varied pattern of chemical change. These alterations depend on the compensatory activities of various extrarenal mechanisms, the presence of complicating factors, such as infection and anemia, and the activity and diet of the patient, as well as on the character and extent of the renal lesions. Hence, it is extremely difficult, if not impossible, to relate specific renal structural alterations to distinctive chemical patterns. It is more convenient to consider the behavior of various substances in the blood during renal insufficiency and to discuss the implications of this behavior.

ELECTROLYTES

The modern dynamic theory of metabolism has developed in the course of studies of the fate of large organic molecules in the body, but a similar point of view regarding mineral metabolism has been widely held for many years. Recent work with isotopic tracers has served to strengthen this view.⁵ Electrolytes within the tissues and in the extracellular fluids are readily exchangeable. Indeed, an active exchange of ions is in continuous operation. The notion that the electrolytes of the cells and extracellular fluid are held apart by more or less rigidly semipermeable membranes is no longer tenable.

This idea has been based on the fact that the electrolytic structure of the plasma and extracellular water differs from that of the intracellular fluid. Sodium and chloride are present in higher concentrations than any other ions in the extracellular

space, whereas potassium and phosphate predominate within the cells. The factors that determine these inequalities of ionic concentrations are obscure. Certainly, there is a demonstrable equilibrium between the ions of the two spaces, a change in the concentration outside the cells provoking a change within. In general, it appears that these changes are most important when alterations of the hydrogen ion concentration and osmotic pressure of the extracellular fluids occur.

Hydrogen Ion Concentration

One of the most carefully adjusted constants of the extracellular fluid is the hydrogen ion concentration^{4, 6-8}. This value is maintained within narrow limits just on the alkaline side of neutrality largely through the activity of buffer salts. These compounds react with strong acids or bases to produce neutral salts and weakly ionizable acids or bases. The carbonic acid-bicarbonate buffer is of special importance. It possesses a remarkably wide buffering capacity, since carbonic acid is easily and quickly excreted through the lungs. Acids other than carbonic acid and all bases must be excreted by the kidney. When renal dysfunction leads to an accumulation of acids or bases in the plasma, a significant change in the hydrogen ion concentration of the plasma ultimately occurs. Under these circumstances more slowly acting secondary measures of defense are brought into play, such as the mobilization of base fixed in bone and the movement of phosphate into the cells. During acid-base imbalance of sufficient magnitude and duration, the compensatory adjustments may, in themselves, prove harmful, producing respiratory abnormalities or malformation of bone. Thus, efficient renal control of hydrogen ion concentration is vital, and when interfered with by disease, may not be readily corrected by extrarenal mechanisms.

The renal regulation of the sodium concentration in the plasma is of major importance in the maintenance of acid-base balance. Since sodium constitutes approximately 95 per cent of the cations of plasma, it plays a prominent role in the establishment of the hydrogen ion concentration. A large number of sodium ions pass through the glomerular filter bed each minute, but active tubular reabsorption prevents the escape of many into the urine.⁴ This activity appears to occur chiefly in the proximal segments of the tubules.

The removal of sodium salts from the glomerular filtrate by tubular reabsorption would be expected to cause alterations in the reaction of the filtrate if reabsorption of the individual members of different buffer pairs were disproportionate. As a matter of fact, it has been held for many years that activity of this character is sufficient to account for urinary acidification or alkalization. According to one view,⁹ the hydrogen ion concentration of the urine is a function of the tubular reabsorption of

sodium bicarbonate. The chief weakness of this hypothesis lies in the assumption that tubule cells are impermeable to carbonic acid, a substance known to penetrate most cells with great ease.⁴ Another theory^{10, 11} places emphasis on the monosodium-disodium phosphate buffer pair, postulating that the monosodium species is reabsorbed selectively under conditions of alkalosis, with subsequent excretion of large amounts of sodium as the disodium salt. In acidosis the reverse is believed to occur. It may be noted that both hypotheses stipulate that all the hydrogen ions available for excretion must be present in the glomerular filtrate. The kidney tubules may then manipulate it as the situation demands. Pitts and Alexander¹⁰ have found that only about 30 per cent of the hydrogen ions excreted during acidosis could be accounted for on the basis of filtration alone. Hence, they concluded that hydrogen ions must be excreted actively by the tubule cells, a conclusion Smith¹ had reached, on theoretical grounds, in 1937.

The important study by Pitts and Alexander,¹⁰ indicating that the kidney can conserve a large amount of base by the simple expedient of exchanging hydrogen ions for sodium ions, has succeeded in clarifying, to a certain extent, the mechanism by which the exchange is effected. It is known that the kidney contains a high concentration of carbonic anhydrase, in common with the red cell, pancreas and gastric mucosa.¹² The ready availability of carbonic acid in tissues for the donation of hydrogen ions suggested that carbonic anhydrase might be concerned in the activity of making hydrogen ions more easily obtainable from this source. This chain of logic was completed by the finding that the administration of sulfanilamide, a well known carbonic anhydrase inactivator, was followed immediately by a markedly diminished secretion of hydrogen ions despite the presence of acidosis. It is possible that a similar inactivation occurs during renal insufficiency. The results of study in this direction should be of great interest.

A second, more slowly acting device by which the kidney reduces loss of base in the urine during the excretion of acidic ions, has been known for a long time and has been found to be deranged during renal insufficiency.¹³ This is the renal synthesis of ammonia and the replacement of cation by ammonium, the manner in which this mechanism is disturbed is unknown, although it appears, like the secretion of hydrogen ions, to involve interference with an enzyme system. For many years it has been widely believed that ammonia is derived from the hydrolysis of urea in the kidney¹⁴ and that the urea clearance requires correction on the basis of urea lost in this activity. A considerable amount of work has cast doubt on this belief. Previously, the major argument for the view was the reciprocal relation between urea and ammonia excretion, which is apparently fortuitous.¹⁵ In addition, only a

negligible amount of isotopic nitrogen derived from urea appears in urinary ammonia, whereas isotopic nitrogen placed in any amino acid appears soon after its administration in high concentration in the urinary ammonia.³ Thus, it seems certain that ammonia is derived from the deamination of amino acids in the renal tubular cells. Van Slyke and his associates¹⁸ recently found that approximately 60 per cent of the urinary ammonia arises from the plasma amino acid glutamine, which is broken down to ammonia and glutamic acid by the enzyme glutaminase. The remainder of the ammonia is derived from other plasma amino acids. The formation of ammonia begins slowly, some time after the establishment of a demand, in terms of excess acid for excretion, and once inaugurated continues for a short time after the need for it has vanished.^{7, 17} A considerable saving of base is effected through this process, amounting under extreme conditions of acidosis to about 75 per cent of the acid cleared.¹¹ The failure of the tubular cells to manufacture ammonia during renal insufficiency may indicate a loss of cells concerned in this activity or enzyme inactivation.

Acidosis usually develops at some time in the course of nearly every case of renal insufficiency.¹⁹ Rarely, no abnormality of the acid-base balance occurs, and even less often, an alkalosis develops.¹⁹ There is no typical pattern of electrolyte change that produces these states. In fact, almost any conceivable arrangement of electrolyte concentrations may appear, not only in different persons but also in the same patient at various times during the course of chronic renal failure. The retention of anions, such as chloride, sulfate, phosphate and organic acid radicals, may contribute to the acidosis, but the loss of base, largely sodium, because of the failure of base-saving mechanisms, accounts for the usual reduction of the carbon dioxide combining power. When chloride accumulation occurs it is often the result of overenthusiastic treatment with isotonic saline solution, since chloride ions are present in normal saline in higher concentration than in the plasma.²⁰ On the other hand, the loss of chloride may be excessive, causing evidence of alkalosis together with signs of peripheral circulatory collapse due to the loss of fluid with the chloride.²¹ Alkalosis during renal insufficiency may also follow excessive loss of chloride in vomitus.¹⁹ Usually, however, vomiting leads to an equivalent loss of base, since gastric secretion of acid is reduced in uremia.²²

Sodium, Chloride and Osmoregulation

The behavior of sodium, chloride and water in the body cannot be discussed separately, since the fate of each is intimately related to the destiny of the others.^{4, 6-8, 23, 24}

In the normal state both sodium and chloride are confined for the most part to the extracellular space.

Nevertheless, the small concentration of sodium within the cells may play a role in the support of the extracellular fraction, since the total bulk of the cells permits them to hold a significant quantity of sodium.²⁵ Chloride is almost entirely extracellular, although it moves in and out of the red cell with ease. Bone contains about a third of the sodium of the body in its interstitial spaces.⁸ This base is available for use in combating salt loss and deficiency, but it is primarily of value in disorders of prolonged duration, such as renal insufficiency, since its mobilization is relatively slow.

Water, of course, is distributed throughout the body tissues, but the proportional distribution is a function of the osmotic pressures in the intracellular and extracellular compartments. The osmotic pressure of extracellular fluid is largely a function of the concentrations of sodium and chloride, whereas that within the cells is determined by the concentrations of potassium, phosphate and protein.

The factors regulating the osmotic equilibria between cells and interstitial fluid are obscure. Two processes of adjustment have been elucidated. The first, chiefly important from the standpoint of the magnitude of the change it can buffer, is the transfer of water between the cell and the fluid surrounding it. It appears that the movement of water out of the cell compensates for increased tonicity of extracellular fluids, so that the final total change is about half what it would be in the absence of such a fluid shift. Hypotonicity leads to a reverse effect.²⁵ A second compensatory mechanism resides in the apparent ability of protoplasm to control the osmotic pressure of intracellular fluids by altering the ionization of intracellular electrolytes and, perhaps, by changing the configuration of intracellular proteins so that they exert more or less osmotic pressure as the occasion demands.²⁵

Shifts of electrolytes as well as of water may occur. The movement of electrolytes appears to become of importance when osmotic dislocations are large or prolonged. This shift seems definitely to occur under these conditions without the destruction of tissues. Since the total amount of sodium held in the cells is of significant magnitude, the movement of sodium from the cells into the extracellular fluid, together with some potassium, may be valuable in combating hyponatremia and acidosis. On the other hand, it has been found that alkalosis with excess base in the plasma may lead to the transfer of sodium into the cells.^{27, 28}

The factors that determine the distribution of water and electrolytes between the various subsidiary divisions of the extracellular fluid—plasma, interstitial fluid and the like—have been extensively studied.²³ Again, a balance of forces, tending to attract water into the plasma on the one hand and to drive it out on the other, is involved that may be seriously disturbed by renal insufficiency. In addition, such major determinants of water ex-

change as thirst, body temperature regulation, rate of gastrointestinal secretion and arterial pressure depend on equally exquisite balances that may be disturbed by renal disease

The renal excretion of water, sodium and chloride are closely related.⁴ Sodium is conserved or disposed of by the kidney by the processes described above. The tubular cells appear to reabsorb sodium as an independent substance, but the demands of ionic equilibria make this most complicated. In the urine, as in the blood, chloride is the chief anion associated with sodium, but the relative proportions may differ widely. Excessive excretion of sodium carries an excess amount of chloride ion out of the body with it, and the reverse is true. There is no threshold in the ordinary sense, for sodium and chloride are reabsorbed in variable amounts at any plasma level, depending on the requirements of the total body economy. Water is reabsorbed throughout the length of the tubule—in the proximal segment, in association with the reabsorption of various solutes, and in the distal segment, against an osmotic gradient.

Reabsorption of water and salt depends, in the main, on the state of the plasma flowing through the kidney, the amount of material reaching the tubules for reabsorption via the glomerular filtrate and the activity of various endocrine organs.

The first factor is of undoubted importance, since the structure of the plasma is, in the last analysis, the chief stimulus to which the kidney is subjected and under which it is moved to function in various directions. Just how this stimulus works is almost entirely unknown. Certainly, a deficit or excess of sodium or chloride in the plasma quickly elicits greater or less activity of the tubule cells in withdrawing these substances from the filtrate even when there is no added stimulus in terms of acid-base imbalance. Likewise, it has been shown that a factor of plasma concentration operates in determining the renal reabsorption of water.²⁹

The second factor is somewhat more accessible to study with the available technics. Two aspects of this activity require consideration. First, the character of the filtrate is essential in determining reabsorptive activity. When substances such as potassium, sulfate and glucose appear in the filtrate in higher concentrations than normal, a diuresis results in which an excessive amount of sodium, chloride and water is lost. Secondly, the relation between the volume of glomerular filtrate and the capacity of the tubules to handle it is significant, particularly in pathologic processes that may interfere with the normally prevailing balance.³⁰ Reduction of filtration without concomitant reduction of tubular capacity, as in acute diffuse glomerulonephritis, may result in excessive reabsorption of water and electrolytes, whereas greater destruction of tubular cells than of glomeruli may lead to the so-called "tubular

diuresis." Likewise, a normal renal circulation is necessary for glomerulotubular balance.

It now seems clear that tubular reabsorptive activity is controlled, in part, by the activity of the endocrine system, the more important organs being the adrenal cortex and the pituitary gland. The role played by the former is best seen in the derangements that follow disease of the adrenal cortex. In Addison's disease it has been found that sodium loss is excessive because the renal tubules fail to reabsorb sodium owing to a deficit of cortical hormones, similar to, if not identical with, desoxycorticosterone acetate.³¹ In addition to sodium loss, potassium retention occurs. The fundamental change in the plasma concentrations of these two ions appears to account for many of the manifestations of the disease. Desoxycorticosterone in excess produces a syndrome of a contrasting character in which potassium is lost.³² Occasionally in Cushing's syndrome, a disorder in which hyperactivity of the adrenal cortex seems probable, hypopotassemia and sodium retention may occur.^{33, 34} There is no doubt that the pituitary gland elaborates substances having a powerful influence on renal tubular activity. The antidiuretic hormone is active in promoting the reabsorption of water and is necessary for normal water excretion. The absence or deficit of this agent has been shown to be responsible for the defect of water reabsorption in diabetes insipidus. This hormone, like the cortical hormone, has an influence on the tubular reabsorption of sodium and chloride.³⁵ Thus, there appears to be an excessive reabsorption of sodium in pituitarectomized animals that leads to edema formation when salt is added to the drinking water. The pituitary gland is also active in affecting other renal tubular functions, for it has been shown that the excretion of Diodrast and other substances is reduced following pituitarectomy³⁶ and enhanced by the administration of pituitary extracts.³⁷

Renal insufficiency may result in the loss or retention of water and salt, depending on the character of the renal lesion. Early in the course of renal disease, glomerulotubular imbalance may lead to increased reabsorption of water and salt, whereas later in the course, tubular diuresis results in loss. Since each of these substances is handled by more or less independent mechanisms, salt may be lost in excess of water or water in excess of salt, or the two may be retained independently in some degree.

Water and salt retention with the formation of edema occurs frequently in the course of many renal disorders, often in association with other evidence of renal failure. In the nephrotic syndrome, edema arises primarily from the renal loss of plasma protein with a resulting disturbance of the transcapillary balance of forces. In acute diffuse glomerulonephritis, edema apparently stems from the renal retention of water and electrolytes, although this

point is disputed by those who claim that congestive heart failure may be a factor³⁸ In this instance, a reduction of the glomerular filtration rate relative to the capacity of adjoined tubules is the cause of excessive reabsorption, as well as of azotemia It seems not unlikely that heart failure in such cases is the result rather than the cause of factors producing edema

Occasionally, renal failure results in retention of sodium and chloride, with loss of water³⁹ This situation, which is usually found when the structure of the kidney is not seriously disturbed by disease, probably implies an abnormality of water reabsorption in the distal segment The plasma and the extracellular fluid as a whole become demonstrably hypertonic Winkler and his co-workers⁴⁰ have shown, in a series of carefully planned experiments, that such a hypertonicity leads to the loss of water from the cellular compartment, probably accompanied by intracellular electrolyte This cellular dehydration at first is not serious, but it ultimately causes sudden death from respiratory failure^{40 41} Certain deaths in renal insufficiency in the absence of acidosis or cardiovascular abnormalities may occur on this basis

Recently, several interesting cases have been reported in which renal insufficiency, due to sulfonamide intoxication, was associated with severe injury to the brain and increased plasma concentrations of sodium and chloride Luetscher and Blackman³⁹ described 5 patients who developed oliguria and azotemia after the administration of varying amounts of sulfonamides In all, signs of central-nervous-system injury, such as confusion, delirium, stupor and coma, were observed Marked elevations of the serum chloride and sodium developed as the oliguria and azotemia receded, apparently because of excessive water loss in the urine without a corresponding loss of sodium and chloride It appears that the therapeutic administration of saline solutions had nothing to do with this phenomenon However, in 2 cases, death, as a result of pulmonary edema, followed the cautious intravenous administration of fluid At autopsy, areas of cerebral edema and gliosis were found, together with renal tubular lesions and thrombosis of the interlobular veins In 2 patients who survived the uremic stage, there was a slow and incomplete recovery from the effects of the central-nervous-system lesions

Symptomatology of this character may also follow overzealous administration of saline postoperatively⁴²⁻⁴⁴ Apparently, renal dysfunction, on the basis of incipient surgical shock, becomes more profound and uremia develops when the necessity for coping with large amounts of salt and water is superimposed Edema frequently develops Likewise, ill considered therapy may precipitate or intensify uremia when renal parenchymal damage is present.

In conditions such as diarrhea, pyloric obstruction and excessive sweating, dehydration may be associated with a loss of electrolyte in excess of water, especially when water is ingested without a supplement of salt Dilution of the plasma occurs, and water moves from the extracellular space into the cells When the loss of body water is sufficiently large, the plasma volume may be reduced Dehydration of this character occurs frequently during renal insufficiency The loss of the concentrating power and the failure of electrolyte-sparing processes lead to large losses of water and salt and usually result in acidosis

Recently, Thorn, Koepf and Clinton⁴⁵ described in detail 2 cases of so-called "salt-losing nephritis" The patients were admitted to the hospital in a state of shock, associated with azotemia and hyposthenuria A provisional diagnosis of Addison's disease in crisis was disproved in each case by a failure to improve after the administration of desoxycorticosterone acetate The administration of sodium chloride was followed by alleviation of the symptoms of collapse, but by no change in the signs of renal insufficiency Both patients ultimately died in uremia with hypertension In these patients, it appeared that the loss of sodium and chloride as a result of tubular damage, possibly associated with glomerulotubular imbalance, induced a rapid loss of water and a critical reduction of the plasma volume Such cases are rare Usually, there is a progressive dehydration The ingestion of water finally fails to correct this loss, and a state of lassitude, weakness, integumentary and mucosal drying and hyperpnea slowly develops

Hypochloremia is characteristic of these cases and is often observed during renal insufficiency⁴² Excessive salt loss, without serious depletion of the plasma volume, may produce a syndrome of muscle cramps, weakness, fatigability, apathy and mental confusion, as in heat cramps⁴⁶ Psychiatric disturbances in normal men suffering from protracted salt deficiency have been shown to respond to increases in salt intake⁴⁷ Thus, it is evident that routine restriction of salt when edema is not present may have serious consequences in uremic patients

Potassium

Potassium is the most important base held within the cells In this position it plays an essential role in the determination of intracellular osmotic pressure and water content Moreover, it apparently participates in some manner in the processes of intracellular metabolism⁴⁸

Reduction of potassium ion concentration in the fluid bathing muscle is known to cause decreased irritability It is possible that this factor is significant in the syndrome of familial periodic paralysis⁴⁹ This condition is characterized by periodic hypokalemia associated with losses of motor function, reflex activity and electrical excitability that im-

prove dramatically following potassium administration. This response appears to be specific, but its mechanism is not entirely clear, since hypokalemia of the same order does not usually cause paralysis, except in susceptible persons.⁴⁹ A similar state, however, has been produced in animals treated with desoxycorticosterone.⁵² Low serum potassium levels likewise cause abnormalities of cardiac muscular activity, giving rise to electrocardiographic changes consisting of depressed ST segments and low T waves.⁵⁰ Necrotic lesions of the myocardium have been induced in rats by overdosage with desoxycorticosterone and low-potassium diets.^{51, 52}

It is now evident that sufficiently high levels of potassium are also injurious to the heart.^{53, 54} In animals and men, anomalies of conduction occur when the potassium level exceeds 10 milliequiv per liter. These abnormalities result in increased height of the T waves, widened QRS complexes and evidence of progressive ventricular block. Death occurs in heart failure with cardiac arrest. No other manifestations of abnormal neuromuscular activity have been noted.

The study of potassium metabolism has suffered from the complexities inherent in the activity of this ion.⁴⁸ The relation between tissue and extracellular potassium, the balance between intake and renal excretion and the influence of the endocrine system are difficult to disentangle. Thus, the potassium clearance may change markedly from day to day in the same person and the plasma concentration may vary unpredictably, often without reference to potassium intake.⁵⁵ Since most of the potassium of the body is held within the cells, relatively small shifts of the ions into or out of the extracellular fluid might be expected to produce significant plasma concentration changes. On the whole, a dynamic balance appears to exist between the two major water compartments that permits active exchange of potassium.^{48, 56} Moreover, mass shifts may occur in response to alterations of water concentration or of tissue catabolism. These factors undoubtedly account for the apparently erratic behavior of plasma potassium.

✓It is possible, in view of recent evidence^{57, 58} that potassium is lost by the cells during acidosis. Apparently, the movement of potassium from the body during acidosis due to diarrhea in infants demands replacement therapy.⁵⁹ Recovery is more rapid and fatalities fewer under this regime. It is not unlikely that a similar situation arises during renal insufficiency when there is wastage of electrolytes. This may ultimately pose a problem of therapy in renal disease.

Ordinarily, the kidney does not permit excessive loss of potassium in the urine. The renal clearance is quite low, indicating extensive tubular reabsorption.⁴ When potassium is injected intravenously or given by mouth, however, the kidney excretes it rapidly. Although it is apparent that potassium is

handled independently of sodium by the kidney, some may be lost during a sodium diuresis. Satisfactory quantitative studies of potassium reabsorption have not been made.

Renal disease does not usually result in disturbances of potassium until it is far advanced.^{55, 60} Indeed, retention does not occur until anuria or extreme oliguria has developed.⁶⁵ This fact does not necessarily denote normal renal excretory function. Reduced tubular reabsorption may easily compensate for the reduction of filtered potassium and, indeed, seems evident in the demonstration by Keith and his co-workers⁵⁵ of potassium-inulin clearance ratios at or in excess of unity. These investigators suggest that the high ratios indicate tubular excretion, but in view of the questionable validity of the inulin clearance as a measure of filtration rate during renal insufficiency,⁶¹ this conclusion cannot be accepted. Although urinary loss of potassium might be anticipated, it has been observed less frequently than retention.

Potassium intoxication during uremia is as rare a therapeutic complication as it is a spontaneous development. Electrocardiographic changes and even fatalities due to cardiac arrest have been described following the use of potassium chloride for the purpose of inducing diuresis.^{62, 63} As a rule, dangerous retention does not occur, but the drug must always be given with caution when azotemia is present and never during anuria.⁶⁴ Spontaneous elevations of potassium, with sudden death, have been reported in chronic renal disease and in anuria.^{65, 66}

Recently Brown, Currens and Marchand⁶⁷ reported 3 cases with low potassium levels during chronic nephritis. In these patients episodes of apparent flaccid paralysis associated with electrocardiographic changes characteristic of hypokalemia were observed. Potassium chloride therapy was followed by symptomatic improvement and a return of the electrocardiogram to normal. Potassium-balance studies were not carried out. Although these findings resembled those of familial periodic paralysis, certain discrepancies were noted. On several occasions the episodes of motor disorder were characterized by stiffness and cramps that might have been caused by hypocalcemia or hypochloremia, which were present. Moreover, none of the patients presented the characteristic loss of tendon reflexes. In view of these divergencies and since it is difficult to induce the syndrome experimentally in human subjects, the conclusion that potassium depletion was responsible for the episodes of paralysis must be accepted with caution. Other cases of potassium depletion in which neuromuscular manifestations did not develop have been reported.^{68, 69}

Like sodium and water, potassium is subject to the influence of the endocrine system. The adrenal cortex is particularly active in this respect, produc-

ing an agent, like desoxycorticosterone, that stimulates the renal tubular reabsorption of potassium^{31, 32}. In the absence of the kidney this agent apparently has no effect on the plasma potassium concentration⁷⁰. It has been found, however, that potassium depletion⁷¹ or desoxycorticosterone may be effective in prolonging life during experimental renal insufficiency^{72, 73}.

(To be concluded)

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C CABOT

TRACY B MALLORY, M D, *Editor*

BENJAMIN CASTLEMAN, M D, *Associate Editor*

EDITH E PARRIS, *Assistant Editor*

CASE 32471

PRESENTATION OF CASE

A thirty-seven-year-old factory manager entered the hospital because of general malaise.

The patient was apparently well until four and a half months before entry, when he began to feel tired and "washed out." His job was trying at that time, and he returned home each evening with an extremely "tired," aching feeling in the legs. The aching became most marked when he sat with the legs hanging down, but there was no concomitant swelling of the ankles. Four months before entry, he developed a diffuse, crampy pain in the right upper quadrant of the abdomen. This was followed by tenderness in the same region and fever, the white-cell count was 18,000. The patient was taken to a hospital, where an inflamed appendix, located almost at the level of the umbilicus, was removed. He recovered rapidly and felt much better after the operation. Three and a half months before entry, several days after his return home, he was suddenly seized by a severe, sharp pain in the left back that was aggravated by breathing and was not relieved by strapping the back. He also developed increasing dyspnea, fever, prostration and a hacking, non-productive cough. After a week in bed with little improvement, he again entered the hospital. A chest x-ray film showed a large pleural effusion on the left, and 200 cc of pink fluid was removed. Six weeks before entry another chest film showed the diaphragm to be high on the left, there was considerable density in the left lower lobe and a small amount of fluid, with what seemed to be a pocket of air, in the left pleural cavity. For the next six weeks the patient had profuse sweats day and night. On one occasion he coughed up a small amount of blood. The chest pain gradually subsided under penicillin therapy. On discharge from the hospital, four weeks before entry, he was afebrile but he still had a mild cough, poor appetite, weakness and a sense of constriction in the left side of the chest. He resumed work on a part-time basis but was forced to stop because of marked fatigue. Three weeks later, x-ray films taken by a physician showed little change

from the findings on the previous examination except for slightly less pleural thickening.

The patient had always enjoyed good general health. He smoked about forty cigarettes a day and had five to seven drinks each evening. Since the onset of his illness he had lost about 30 pounds in weight.

Physical examination revealed a pale, sickly looking man in no distress. The left side of the chest, which was sunken in front, expanded only slightly on deep inspiration. Breath sounds were diminished over the base posteriorly. There were no moist or musical rales. There was tenderness in the right upper quadrant. The liver edge was somewhat tender and was palpated one and a half finger-breadths below the costal margin.

The temperature was 98.6° F, the pulse 96, and the respirations 20. The blood pressure was 135 systolic, 70 diastolic.

Examination of the blood showed a hemoglobin of 15.1 gm and a white-cell count of 9400 with 62 per cent neutrophils and 36 per cent lymphocytes. The urine was normal. X-ray examination of the chest showed a cavity containing air and fluid in the left side of the chest laterally, extending from the level of the fifth rib to the diaphragm. The cavity measured 3 cm in the anteroposterior view and 10 cm in the lateral view, with the fluid level at the eighth interspace. There was gross thickening of the axillary pleura, and the left diaphragm was elevated. The right lung field was clear, and the heart was not displaced. Bronchoscopy showed a good airway on the left, with no evidence of obstruction.

A needle inserted high in the right midaxilla went through thickened tissue and then into the air pocket seen on the x-ray film. The pressure with normal breathing was equivalent to +1 to -1 cm of water, but with deep inspiration it swung to -7 cm and with clearing of the throat it swung high enough on the positive side to force fluid out of the top of the manometer. After 60 cc of air had been removed from the cavity, 25 cc of thin, slightly cloudy fluid was withdrawn, toward the end the fluid was slightly pink. It contained 4600 red cells and 6400 white cells per cubic millimeter, all of which were polymorphonuclears. Chest x-ray films after the tap showed a slight decrease in the amount of fluid. On the fifteenth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. ALLEN BRAILEY. I do not know when I have read a more delightfully tangled web of clues and counterclues, real and spurious. This man's illness began with a tired, achy feeling in the legs. A month later he was suddenly seized with severe, sharp pain in the left back, — I assume that the term "left back" means the left lower chest in back. It would be easy to explain these particular symptoms as

having been due to thrombophlebitis of the lower legs, with subsequent pulmonary embolus. And he may have had both thrombophlebitis and embolism, but these events rarely occur in men under forty and the description of the chest pain does not sound much like embolism. It suggests pleurisy due to infection rather than infarction, for the record states that following the chest pain of sudden onset he developed increasing dyspnea, fever, prostration and cough. X-ray examination showed a large pleural effusion, and subsequent events suggested that the fluid removed from the pleura was infected and became an empyema. Effusion of more than a few cubic centimeters in association with pulmonary infarction is exceedingly rare, and empyema following an embolus from an early symptomless thrombophlebitis of the leg veins is, I think, unheard of. Consequently, if the patient had a pulmonary infarct of the usual leg-to-lung variety, I can only say that he had much else besides, and I do not know how to relate such an infarct to whatever else was present.

Let us drop the origin of the illness for the time being and consider the end result. Besides the effusion and empyema that were suspected, we are told that there was considerable density in the left lower lobe, that the left leaf of the diaphragm was high and that the left side of the chest seemed sunken in and showed little respiratory excursion. These observations can mean only that the lower lobe was largely collapsed owing either to increased pressure in the pleural space or to bronchial obstruction with absorption of the air behind the obstruction. The first x-ray examination revealed a large effusion, but the second plate demonstrated only a small amount of pleural fluid. Yet the lower lobe had not re-expanded, and the diaphragm had already risen to an abnormal position. The bubble of air seen in the left pleural space could easily have been drawn in on the occasion of the first thoracentesis. But it was not absorbed, it persisted, and in fact, the record suggests that it was distinctly larger when last observed than when first observed. Finally, there is the detailed information concerning the pressure found on the occasion of the last thoracentesis. It is possible, of course, for a pleural effusion to reach the precise volume to neutralize the negative pressure normally found in the pleural space, but it would be a most striking coincidence to have pressure readings taken at exactly the time when the intrapleural pressure was so neutralized. The fact that the pressures found on quiet breathing oscillated around zero ordinarily means only one thing: that the pleural space is in direct connection with the outside by way of a bronchopleural fistula. The fact that deep inspiration produced a negative pressure of 7 cm. of water suggests that the fistulous tract was small. But if there was a bronchopleural fistula, there was no bronchial obstruction. Therefore, why did the lobe collapse? First of all, collapse

does not require that the bronchus be completely obstructed. It simply requires that the cross section of the airway be reduced below a critical area. Furthermore, there is another possibility that we have not considered. Perhaps we are not dealing with normally elastic lung tissue. Perhaps this lower lobe or a good portion of it had been replaced by scar or by cancerous tissue. Cancer that had reached the pleura could and probably would have resulted in pleurisy with effusion, as well as in a fistulous tract between the pleura and a bronchus. What else can we find in favor of cancer? On the first chest tap, 200 cc of pink fluid was removed. Presumably it was bloodstained fluid. The blood may have resulted from the trauma of the tap. But the last tap is described as follows: "25 cc of thin, slightly cloudy fluid was withdrawn, toward the end the fluid was slightly pink." This account certainly suggests that the effusion contained a little blood that had settled into the lower portion of the cavity and that the blood was not the result of a traumatic tap. Also, after the early empyema had been successfully treated with penicillin, the patient did not do well, but in spite of being afebrile, he continued to have a mild cough, poor appetite and weakness, and he had to give up work because of marked fatigue. He is described as pale and sickly looking — symptoms and an appearance that are consistent with an advancing cancer of the bronchus.

What other diagnoses must be considered? Could the whole process in the chest have been due to tuberculosis? Perhaps it could. The location of the process and the speed with which it incapacitated the patient are unusual but not unheard of. If he had tuberculosis, however, the empyema was a tuberculous empyema, and even if due to mixed organisms it would not have responded so favorably to penicillin as this one apparently did. When the patient entered this hospital he was afebrile. Yet he was a very sick man and getting sicker. If the disease had been tuberculosis, he would certainly not have been afebrile at that stage. Finally, I am sure that appropriate laboratory tests were made to exclude tuberculosis, and since they are not even mentioned I am sure that they were negative.

Did the appendicitis have anything to do with the disease on admission? The patient may have had an abscess of the left lobe of the liver or a subphrenic abscess as a complication of the appendicitis, with subsequent rupture through the diaphragm to involve the pleura and the left lower lobe. The liver is described as somewhat enlarged and tender. This seems a rather fanciful hypothesis, and furthermore it is open to the same objection that during the hospital stay there was little evidence that infection was playing any major role. Yet the patient was not getting better.

Did he have a lung abscess of the ordinary gangrenous variety that ruptured into the pleural space? I should like to know how much sputum he raised,

whether it had any characteristic odor and what was the odor of the pleural fluid. Nothing is said of a fluid level inside the lung. Lung abscess is a poor guess. I think that the best I can do is to guess that at operation the left lower lobe was removed, or at least biopsied, and that cancer was found.

I do not know why I refused to see the x-ray films. Perhaps I should see them now.

DR JAMES R. LINGLEY: This first film, which was taken in the other hospital, shows the large pleural effusion on the left. This film was taken two months later and shows the air-containing cavity with a fluid level at the eighth rib. The first film taken here shows little change from the one taken a month previously. The cavity looks like a pleural rather than a pulmonary cavity. There is marked thickening of the axillary pleura, which suggests an empyema rather than an effusion. The lower lobe is not well visualized because of the change in the pleura, but it is probably partially collapsed. I think that the degree of collapse can be due to pressure from an empyema.

DR DONALD S. KING: I first saw this patient in my office. After he was admitted to the hospital, I discussed the case with the members of the refresher course and later with those of the Thoracic Clinic. The sequence of events seemed to point to the operation as the main etiologic factor. But the sequelae were unusual for a postoperative pulmonary infarct, and we all wondered whether some pre-existing condition accounted for the lung changes. I believe that most of the trouble before the operation was on an emotional basis. A man who smokes forty cigarettes a day and takes eight drinks of alcohol usually has something on his mind, and I know that this patient had plenty of things to worry him. Dates are important in consideration of this case. On May 29, the appendectomy was performed. He went home a few days after the operation. When he was at home, on about June 5, he developed a sudden pain in the left back and fever. On June 26 the x-ray film was taken that showed the large left pleural effusion. On June 27 the first chest tap was performed. On August 16 the x-ray film was taken that showed the pocket of air and fluid in the pleural cavity and the so-called "thickened pleura." On September 17 another chest x-ray film was taken that disclosed the persistence of the air pocket, his physician therefore reasoned that he must have a bronchial fistula and sent him to the hospital for study.

On physical examination we were impressed by the markedly diminished respiratory movement of the left side of the chest. The patient said that this loss of motion was becoming more and more noticeable. It seemed evident that unless something were done a permanent crippling would result. Consequently, after the chest taps, Dr. Churchill arranged to operate. I saw Dr. Churchill remove part of the lung and decorticate a considerable area. I

do not yet know what Dr. Mallory found when he examined the specimen. The only clinical explanation that I can give is that there was an aseptic pulmonary infarct, which was, as practically always, located close to the pleural surface, and that the area became necrotic and ruptured into the pleural cavity. There is no indication of the formation of a real putrid abscess in the area of an aseptic infarct. Cases are reported, however, in which such a condition is said to have developed. Do you believe that this can happen, Dr. Castleman?

DR BENJAMIN CASTLEMAN: Rarely.

DR KING: Recently, I read a paper that quoted you to that effect but went on to report a series of cases in which it was determined that true abscess had developed. But in this case there is no history of abscess.

DR LOUIS K. DAHL: I should like Dr. King to comment on Dr. Brailey's statement that pulmonary infarcts do not give pleural effusion. It is my impression that they frequently do.

DR BRAILEY: I do not believe that they cause empyema—that is, no more than a small amount of fluid. Dr. Homans was my authority.

DR KING: I am sure that large pleural effusions occur in association with pulmonary infarction. The cases that I remember particularly are those with post-delivery infarction, in which the fluid has been bloody. But I agree that, in a large series of pulmonary infarcts, the percentage in which a massive effusion occurs is small.

DR TRACY B. MALLORY: Dr. Churchill, will you tell us what you thought before operation and describe your operative findings?

DR EDWARD CHURCHILL: I do not wonder that Dr. Brailey found this a confusing case. Even after working in this man's chest for three hours I was still confused. Surgically, we were faced with two or three facts that led us to the treatment, irrespective of what we might call a rational basis for the interpretation of the disease. The patient had little respiratory excursion, owing to a frozen chest. He had been out of work and could not go back; he had tried conservative measures for about four months and finally concluded that he was making no progress.

I shall give you only the objective findings of the operation. In resecting the seventh rib I found the ribs close together and beginning to "shingle," as they do in chronic pleuritis. By a slow dissection of the thick parietal pleura, we were able gradually to spread the thoracotomy opening and expose the field. There was an air-filled cavity lined with pleura, about 1 cm thick. The cavity contained another 2 or 3 cc of the pinkish, cloudy fluid that Dr. King had removed. There was a membranous inflammatory partition within the cavity, which was easily opened. There was about 1 cm of rather thick, purulent material on the surface of the lung. That material was put into a test tube and sent over

for immediate smear and culture. The smear was negative, as had been both anaerobic and aerobic cultures from the fluid removed by Dr. King prior to the operation. We set ourselves the task of dissecting away the thickened pleura surrounding the cavity. This was extremely dense and slightly edematous and effectively bound down the lung. On the anterior surface of the lower lobe was an area where there was no thickened pleural membrane. Instead, there presented an area of the lung with thin visceral pleura and anthracotic markings. On making a slight incision the alveolar spaces were found to be filled with exudate. After cutting away the thickened pleural capsule, we were left with a "button" of lung surrounded by a fringe of thickened pleura. I therefore took a tangential slice off the lung to include the areas described. Cutting at a depth of about 1 cm. below it, the knife passed through normal aerated lung tissue with brisk pulmonary circulation and open bronchi. The process consequently did not extend deeply into the lung as one might expect had it been hemorrhagic infarction. I hope that we cured the man. When he left the hospital, the chest was moving freely and he felt better. We straightened out the lower lobe, liberated the diaphragm and restored the chest to as nearly normal as possible. We shall await Dr. Mallory's report before trying to interpret the disease.

CLINICAL DIAGNOSIS

Empyema, left chest

DR. BRAILEY'S DIAGNOSIS

Bronchiogenic carcinoma

ANATOMICAL DIAGNOSES

Infarction of lung (? septic).

Fibrous pleuritis

Chronic pneumonitis

Bronchiolectasis

PATHOLOGICAL DISCUSSION

DR. MALLORY. I am not sure that I am going to help much in the interpretation, as so often happens in cases that are rather obscure clinically. I shall try to show what Dr. Churchill found. A piece of white tissue represented what was left of the greatly thickened pleura. In the center was a mass—the "button"—projecting through the gap in the dense fibrous tissue—that had the appearance of lung tissue. Microscopic sections from this area showed that the thickened pleura was merely dense granulation tissue of the type that one sees in the wall of an empyema cavity or an organized hematoma. The nubbin of herniating lung tissue was completely necrotic and looked rather like infarction, although its character was different from the ordinary infarction. The average infarct of the lung is deeply hemorrhagic and firm. This tissue was soft, and

blood pigment, if it was present, had been largely absorbed.

The specimen that Dr. Churchill gave us also included a certain amount of underlying lung tissue that showed a complicated picture. There was an extensive chronic pneumonitis, as well as some large dilated bronchioles surrounded by marked inflammatory infiltration. This was a superficial specimen, and I think that the presence of such large bronchioles must be considered as indicating bronchiectasis. There was also an area in the deeper lung tissue that showed dense scarring, with concentration of elastic fibers, which is characteristic of healed infarction. Finally, there were a number of blood vessels containing organized thrombi. I am certain that there was infarction in this case. I am tempted to believe that there was some preceding pneumonitis of much older duration than the history indicated, although I am not entirely certain about that. Why the wall of the empyema cavity contained a gap and the lung herniated through that gap, I cannot guess, unless the wall had been lacerated in one of the preceding taps. The wall was so thick, however, that I find it difficult to believe that a needle could have produced a laceration 2 cm. long.

Have you any further comments, Dr. Churchill?

DR. CHURCHILL. There is one variable here that I think we must remember, although I cannot be certain of its significance. If we start at the beginning with an ordinary post-infection empyema, such as may occur after a superficial carbuncle, a mastoiditis or an appendicitis, we know that the empyema would probably develop a bronchial fistula because it has originated from a small abscess beneath the visceral pleura. If the empyema in the case under discussion had been recognized at that time, if a streptococcus had been cultured and if a surgeon had drained it, I think that our findings would have been accepted without any confusion. Actually, what did happen? The illness was treated with penicillin, and we have no record of a positive culture. I cannot picture this type and degree of chronic pleuritis originating other than by invasive infection. I state it as a series of questions. Was there a small metastatic abscess—possibly an infarct, because it was borne by the blood stream but not in the sense of a hemorrhagic infarct associated with thrombophlebitis—beneath the visceral pleura that caused the empyema? Was the invasive infection brought under complete control by chemotherapy? Did the rupture of this abscess produce the chronic pyopneumothorax and the chronic pleuritis? Having had difficulty in cutting the pleura with a knife or scissors, I cannot see how it could have been lacerated by an aspirating needle, but what the mechanism was that left the exposed area of lung, I do not know.

DR. KING. You would not have drained early would you? It was very thin fluid—never gross pus.

DR CHURCHILL I do not know

DR KING That fluid could probably have been taken out with a needle

DR CHURCHILL Perhaps if it had been removed with a needle and penicillin had been administered, the result would have been different

Was the patient tapped on the sixth day following operation?

DR KING Two or three weeks afterward The first chest tap was made four weeks after operation

CASE 32472

PRESENTATION OF CASE

A seventy-six-year-old physician entered the hospital because of painless jaundice

Three months before admission, prostration, nausea and vague abdominal pains without diarrhea occurred twelve hours after the patient had eaten a cold salad at a public gathering. He spent two weeks in another hospital, where a barium enema was interpreted as showing ulcerative colitis. One stool examination gave a ++++ guaiac reaction, but a subsequent one was negative. An upper gastrointestinal series revealed a normal appearing esophagus, stomach and small intestine. A single large gallstone was visualized. After this episode the patient never regained his appetite. He lost weight and felt increasingly tired and ill. A diffuse vague abdominal discomfort persisted. There was no change in bowel habits and no chills or fever. Three weeks before admission painless jaundice developed insidiously, and anorexia became more pronounced, the stools became clay colored, and the urine became dark. The patient had been losing weight and feeling tired for six or seven months.

Three years before admission the patient had been admitted to a hospital after an acute episode of vertigo with nystagmus. There were no headaches. For many years he had been accustomed to drinking Scotch whisky and soda at bedtime and three or four highballs during the week.

On physical examination the scleras and the skin were yellow. The heart and lungs were normal. The liver edge was palpated 6 cm below the right costal margin and 12 cm below the xiphoid. The upper border was percussed in the fifth interspace. The left lobe was harder and tenderer than the right. The hepatic surface felt smooth. The abdomen was slightly distended, but there were no signs of fluid. The spleen was not palpable. The prostate was twice the normal size. There were external hemorrhoids.

The temperature was 98.0° F, the pulse 60, and the respirations 20. The blood pressure was 124 systolic, 70 diastolic.

Examination of the blood showed a hemoglobin of 13.6 gm per 100 cc and a white-cell count of 13,000, with 78 per cent neutrophils. The urine

gave a + test for albumin and a ++ test for bile, the sediment contained rare hyaline casts, rare red cells and occasional white cells per high-power field. X-ray films of the gastrointestinal tract showed evidence of an extrinsic mass compressing the lesser curve of the stomach in the region of the left lobe of the liver. The duodenal cap likewise showed evidence of an extrinsic pressure along the lesser curvature margin. There was a suggestion of small esophageal varices. A laminated, round opacity was seen in the region of the gall bladder. The liver was considerably enlarged and the spleen slightly so. The previous films were reviewed by another observer, who failed to find evidence of ulcerative colitis. The serum cholesterol was 188 mg, the non-protein nitrogen 35 mg and the total protein 5.8 gm per 100 cc with 3.5 gm of albumin and 2.3 gm of globulin. The alkaline phosphatase level was 19.3 Bodansky units per 100 cc. The cephaloflocculation test was + in twenty-four hours and ++ in forty-eight hours. The prothrombin time was 22 seconds (normal, 18 seconds). The stools were neutral yellow and gave a negative reaction for blood.

Two days after admission the patient was obviously losing ground. The jaundice became a deep-orange color, and the abdomen became moderately distended. On the fourth hospital day a fluid wave was elicited. On the sixth day, the stools became definitely brown and contained bile. On two occasions the patient vomited small amounts of fluid containing gross blood. There was no sign of massive hemorrhage. On the seventh day the patient was more comfortable and seemed to be stronger. On the eighth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR EARLE M. CHAPMAN We are presented with a seventy-six-year-old physician who had been losing weight and feeling tired for six or seven months. He had the first acute episode three months before entry and developed painless jaundice two months later. On physical examination, there was a palpable mass, apparently somewhere in the epigastrium. It is stated that the left lobe of the liver was harder and tenderer than the right, and on x-ray study this mass appeared to be extrinsic, compressing the lesser curvature of the stomach and duodenum. A single diagnosis seems to be difficult indeed, and I think that we must go through a number of possibilities, any one of which I can name with no assurance.

At this age the story of weight loss, the illness of six months and the mass make one suspect the presence of tumor. What kind of tumor was it? I do not believe that it was carcinoma of the head of the pancreas causing painless jaundice. From all these findings I doubt that it was a lymphoblastoma in the retroperitoneal area that caused pressure on the

biliary system and an obstructive type of jaundice. Was it a primary liver tumor — possibly a hepatoma — that involved the left lobe of the liver? From the description I think that that is a possibility to be seriously entertained.

We must also consider an infectious process. Did the surgeon cure this man at operation? I am curious to know the preoperative diagnosis, because if the surgeon cured him, it is an amazing case. The evidence for infection is not great, but we must certainly think of it, especially when we are told that three months before admission there was a sudden episode of abdominal pain and blood in the stool on one occasion and that ulcerative colitis was suspected. But examination in this hospital did not disclose blood in the stool.

Did the patient have a large amebic abscess involving the left lobe and causing necrosis of liver tissue in that region, with jaundice, and pressure on at least a branch of the biliary system, with signs of obstructive jaundice? We learn that later in the hospital stay the stools changed in appearance and contained bile, so that there must have been a channel through which bile passed.

We know that this man had a gallstone. It is therefore possible that he had other gallstones, one of which formed higher in the biliary tree and lodged in the tributary of the common duct from the left lobe of the liver, thus causing obstructive phenomena in the left lobe.

The important decision to make is whether or not the patient had cirrhosis. I am going to say that it is unlikely in this case, because the signs were those of acute liver injury — the prothrombin time was normal, the spleen was not felt by the examiner and the total protein was normal. If this had been cirrhosis of any duration I am sure that the total protein would have been lowered, since it is usually an important indication of cirrhosis. Possibly, this was a subcirrhotic phase of liver disease. The patient drank Scotch whisky during the last few years, but he was not a wine drinker.

The other conditions that I think of are extremely unlikely. I might name a host of rare diseases, but I do not see how they could be entertained. In conclusion I should like to say that I believe that the patient had a primary tumor of the liver, probably a hepatoma of the left lobe, and that if he had cirrhosis it was of minimal degree and was not a portal cirrhosis of severe extent, I do not really believe that cirrhosis was present, however. My next choice is infection with amebic abscess, and finally the possibility of a stone lodged in a tributary from the left lobe of the liver and causing necrosis of tissue beyond that in an isolated lobe of the liver. One of these things, in the order given, is what I believe was found at operation.

DR. DANIEL ELLIS. If the patient had had a hepatoma, would there not have been more evidence of cirrhosis?

DR. CHAPMAN. It is true that a hepatoma is usually associated with cirrhosis, but it is possible without cirrhosis. I think that the normal protein indicates that the remainder of the liver was normal or almost so.

DR. JAMES TOWNSEND. If the patient had a tumor that completely obstructed bile through the intestine at the time he came in, how do you account for the reappearance of the bile?

DR. CHAPMAN. On a mechanical basis I think that when the patient was staggering around and upright there was pressure on the common duct, but that when he was lying down the pressure subsided and the bile went through.

DR. LAURENCE ROBBINS. What about the presence of varices in the absence of cirrhosis?

DR. CHAPMAN. I really do not know. The record states that there was a suggestion of varices, but that was merely a guess. I do not believe that we can rely on that statement in the face of the other findings.

DR. ROBBINS. I examined the patient and suspected that the tortuosities of the folds of the lower esophagus were varices.

DR. CHAPMAN. That is a matter of interpretation. We often see a suggestion of varices.

DR. ROBBINS. The mass and the defect in the lesser curvature of the duodenal cap were constant during the examination. The gallstone was previously described. The spleen was not large, it was slightly above the limits of normal. It was not typical of the spleens that are usually seen in cirrhosis, but I do think that varices were present.

DR. CHAPMAN. Then, of course, we have the fact that the patient drank Scotch whisky, which I regret to say is again in favor of cirrhosis.

A PHYSICIAN. What about the prostate in relation to tumor?

DR. CHAPMAN. The prostate was enlarged to twice the normal size. From the description, I assumed that it was soft and not irregular. I think that metastases from a prostate of this size are extremely unlikely.

DR. ELLIS. Our reasoning was much like that of Dr. Chapman. We thought that this man had obstructive jaundice and that the diagnosis was most probably cancer. With that in mind we advised him to enter the hospital for exploration. He came in three weeks later. Several striking things were noted in the eight days in the hospital. One was the steady decline in his condition. Although he had absolutely no fluid at the time of admission, in three days he had so much fluid in the abdomen that the abdominal viscera could no longer be palpated. This sudden reaccumulation of fluid was difficult to explain. The physical examination as described may be misleading, but there was no question in the minds of the men who felt the abdomen that the mass was the left lobe of the liver as nearly as one could palpate through the abdominal wall.

As Dr Chapman has pointed out, we thought that the blood chemical findings afforded little basis for a diagnosis of extensive intrinsic liver disease. Again, it seemed that this patient had cancer, and he was explored. The impression about the stools is correct: he had clay-colored stools three weeks before admission and for two days after admission, after which they became brown. At operation the surgeon made an incision about 15 cm long and was able to palpate the liver. The left lobe immediately came into view, and the entire liver had a finely granular surface and was yellowish brown and firmer than normal. The surgeon did not find any mass elsewhere in the abdomen. The gall bladder was not palpated. A fairly large section was taken from the right lobe of the liver for biopsy. The cut surface looked yellow and necrotic in places, and in the biliary tree there was a white, friable substance that was unlike anything we had ever seen. We thought that it was a severe necrotizing process in the liver. We did not believe that it was cancer. Because of the patient's poor condition it was decided that the primary condition was severe generalized intrahepatic disease—that was causing all the symptoms and that he should not have further exploration but should be treated from that standpoint. Therefore, no other exploration was done, and the abdomen was closed. The patient steadily failed and died two days after operation.

CLINICAL DIAGNOSIS

Carcinoma of liver, primary

DR. CHAPMAN'S DIAGNOSES

Hepatoma
Cirrhosis?

ANATOMICAL DIAGNOSES

Hepatoma
Cirrhosis of liver, alcoholic type
Tumor thrombi, portal vein and left hepatic duct.
Ruptured esophageal varix, with hemorrhage into gastrointestinal tract.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The biopsy showed an alcoholic type of cirrhosis as well as a hepatoma. The tumor tissue, which was for the most part necrotic, could be seen in some of the venous channels. At autopsy a few days after operation, the stomach and intestines were full of blood. Apparently, there had been a rupture of an esophageal varix. The spleen weighed 210 gm. The liver at autopsy weighed over 2000 gm, and the right lobe contained diffusely cirrhotic nodules, averaging 2 to 3 mm in diameter, and showed little tumor. The medial aspect of the right lobe, as well as the entire left lobe, was infiltrated with tumor. The portal vein and its radicles within the liver were filled with tumor, which is quite frequent in primary carcinoma of the liver. An interesting finding was the presence of tumor within the left intrahepatic duct. Apparently the tumor had extended through the liver tissue into the bile duct and had produced partial occlusion; it is possible that it had something to do with the change in the color of the stools. There was a stone in the gall bladder but no evidence of stone within the common duct.

BIGELOW'S ORIGINAL ANNOUNCEMENT

On November 18, 1846, the *Boston Medical and Surgical Journal* had the privilege of publishing the first detailed public announcement to the medical profession of Morton's demonstration of surgical anesthesia at the Massachusetts General Hospital on October 16 of the same year. The paper was written by Henry Jacob Bigelow, a Boston surgeon of twenty-eight, who had witnessed the first operation and the second, on October 17, and had forced the issue to disclose the nature of the new agent at the time of a third operation on November 9. In the meantime Bigelow made a brief statement on the subject at a meeting of the American Academy

of Arts and Sciences on November 3. Moreover, the published paper was presumably essentially the same paper as that communicated by Bigelow to the members of the Boston Society of Medical Improvement on November 9, the day on which the third demonstration at the Massachusetts General Hospital took place. This operation, a formidable amputation, must have fully convinced young Bigelow of the simplicity and safety of ether insensibility, even if he was in any way doubtful of its value prior to November 9.

Bigelow's paper is probably the most important medical announcement ever to be so issued and thus brought to the attention of the medical profession, as is pointed out in a paper published elsewhere in this issue of the *Journal*. Although news of the first demonstration had been published in both the *Boston Daily Journal* and the *Daily Evening Transcript* on the next day, October 17, and Bigelow had talked about this and subsequent operations to local societies, the news did not have the ring of complete authenticity until it was printed in a well recognized, although small, accredited medical journal. The standing of the surgeon, John Collins Warren, was of international renown. So was the reputation of young Bigelow's father, Jacob. If the latter's oldest son, Henry Jacob, was not so well known outside Boston, at least his name was accepted, and the clear account, skillfully worded, was a document of prime importance, which was readily snatched up by eager hands in both America and abroad. Morton was indeed fortunate in his official announcer for in a few months "anesthesia," a name given to the state of insensibility produced by ether by Oliver Wendell Holmes in a letter to Morton dated November 21, 1846, became a world-wide procedure. That the first practical application of the method was an epoch-making event was fully recognized by the editor of the *Journal*, Dr. J. V. C. Smith, for there appeared in the same number as Bigelow's paper the following editorial calling attention to the article and its significance.

Operations without Pain.—In the leading article of this day's *Journal*, by Dr. H. J. Bigelow, the profession will notice that an impression exists here in Boston that a remarkable discovery has been made. Unlike the farce and tragedy of mesmerism, this is based on scientific principles, and is held in the names of gentlemen of high professional attainments, who make no secret of the matter.

or manner To prevent it from being abused and falling into the power of low, evil-minded, irresponsible persons, we are informed that the discoverer has secured a patent, and that means were taken to have the same security in Europe even before publicity was given to it here Without further remarks, we cheerfully publish all that has been given us on the subject, and wait with impatience for the decision of the profession in regard to its real value

Bigelow's communication was reprinted the next day in the *Boston Daily Advertiser*, Bigelow had the paper reprinted himself, and the *Hartford Courant* printed it as a supplement to the issue of December 26, 1846 The reprint in the *Advertiser* was sent, with a letter, by Jacob Bigelow to Francis Boott, of London, who arranged for publication in the *Lancet* on January 2, 1847 Robert Liston, aware of Jacob Bigelow's letter, operated on December 21, 1846, "with the most perfect and satisfactory results" The "new gas" had been accepted by competent surgeons, both in this country and abroad, in a few months, so that the editor's "impatience" was not of long duration Medicine's greatest single gift to suffering humanity thus was distributed rapidly and efficiently, even taking into account the rate of communication in vogue in 1846 Bigelow's paper was the announcement that gave authenticity and substance to the gift

PROVERBS 23:20

NEVER, it is safe to assume, have so many people been so conscious of their dietary habits and the difficulty of obtaining various articles of food as during the present year Among the ancient and crowded populations of the earth this difficulty has produced mass hunger and, in places, nearly mass starvation, it is the worst of the famines that have periodically visited these unfortunate peoples In other countries, such as our own, where real want has scarcely been known since the early colonists were reduced to their few kernels of corn, an artificial

scarcity of certain items, resulting almost entirely from the recent attempts at price control, has been succeeded by an uncontrolled price inflation that may send these same articles beyond the reach of many people

During the war, when much of the meat supply was rationed, every excuse was made and practically every disease was used as an excuse to obtain extra rations Subsequently, when meat was still difficult

to obtain, whether because of scarcity or because of high prices, there were no committees to intervene on behalf of the patient with liver damage, with suppurative disease or with other wasting illness As of the fall of 1945, when all foods except sugar were removed from the ration list, it was every man for himself and the devil take the hindmost.

Fortunately the present situation is not so

bad as it seems, for we can now refer to a lesson that was taught us during the war years if we cannot afford meat, we can still get along without it Our protein requirements can be met by a variety of foods besides red meat, and iron in almost any form is the substance best adapted to the prevention and cure of the simple anemias

Red meat is not a necessity in any man's diet it is, in fact, possible to get along tolerably well and to endure at least a reasonable span of years without meat of any color George Bernard Shaw, whose somewhat choleric point of view can certainly not be attributed to overindulgence in the roast beef of Merrie England, has, among others, demonstrated this *Homo sapiens* can, in fact, according to recent observations, do quite well on as little as 50 grams of protein per day, in place of the traditional 70 grams, and of this as little as 5 grams need be in the form of animal protein But this is probably hewing too close to the line for Occidental alimentation, in the East, vast populations have sub-

ted fairly well for centuries, — barring seasons
famine, — and there, even in time of plenty, less
an 10 per cent of the total protein intake is from
animal sources

Appetite and availability of food have largely
etermined our own eating habits, and the eating
abits of a people cannot be taken lightly, the most
ecetic of us enjoys a certain sense of well being
hen sitting before a roast of prime beef or a medium
urion steak We need not pretend, however, that
is a necessity so far as physical health is concerned
or that purpose a serving of finnan haddie or a few
tablespoonfuls of soy beans will do as well

Even if the desperation of our days forces us to
be among the winebibbers, circumstances have at
least spared us from being among the notorious eaters
of flesh

MISCELLANY

NOTES

The following appointments to the teaching staff of Har-
vard Medical School were recently announced Harold
Samuel Albert, of Boston (A B McGill University 1942,
M.D. McGill University 1943), assistant in psychiatry,
Richard William Anderson, of Boston (S B University of
Minnesota 1941, M.D. University of Minnesota 1943),
assistant in psychiatry, Robert Eugene Arnot, of Boston
(A.B. University of Minnesota 1937, M.D. Harvard Uni-
versity 1940), research fellow in psychiatry, Lionel Berk-
er, of Cape Town, South Africa (B S. University of Cape Town
1936, Ph.D. University of Cape Town 1939, M.B., Ch.B.
University of Cape Town 1939, M.D. University of Cape
Town 1944), research fellow in medicine, Bernard Bloom,
of Dorchester (A B New York University 1935, M.D. New
York University 1938), assistant in genitourinary surgery,
Wladislaw Joseph Borkowski, of Wilmington, Delaware (B S.
Villanova College 1939, M.D. Jefferson Medical College
1943), assistant in psychiatry, Thomas Berry Brazelton, of
Waco, Texas (A B Princeton University 1940, M.D. Colum-
bia University 1943), assistant in pediatrics, Harold Brown,
of Boston (A B Harvard University 1940, M.D. Harvard
University 1943), assistant in medicine, Henry Bunting, of
Wellesley (A B Yale University 1932, A.M. University of
Wisconsin 1934, M.D. Harvard University 1936), research
fellow in anatomy, Walter Edmund Campbell, of Provid-
ence, Rhode Island (S B Providence College 1937, M.D.
Jefferson Medical College 1941), assistant in psychiatry,
Russell LeGrand Carpenter, of Medford (S B Tufts College
1924, Ph.D. Harvard University 1928), instructor in ophthal-
mology, Donald Tillinghast Chamberlin, of Brookline (A B
Washington University 1926, M.D. Washington University
1930), assistant in medicine, William Rozelle Christensen,
of Salt Lake City, Utah (A B University of Utah 1938,
M.D. Harvard University 1942), research fellow in biological
chemistry, Theodore Sabin Cobbe, Jr., of Canton, Ohio
(A B Kenyon College 1940, M.D. Harvard University
1943), research associate in comparative pathology and
tropical medicine, William Hamilton Daughaday, of Fram-
ingham (A B Harvard University 1940, M.D. Harvard
University 1943), research fellow in medicine, Patrick
Macarney de Burgh, of Bymble, New South Wales (M.B.,
B.S. University of Sydney 1939), research fellow in bac-
teriology and immunology, Briant LeRoy Decker, of Brook-
line (A B Brigham Young University 1924, M.D. Harvard
University 1930), assistant in medicine, William Anderson
Decker, of Jamaica Plain (A B Harvard University 1936,

M.D. Cornell University 1943), assistant in pediatrics,
Frank James Dixon, Jr., of St. Paul, Minnesota (S B Uni-
versity of Minnesota 1941, M.B. University of Minnesota
1943, M.D. University of Minnesota 1943), research fellow
in pathology, Brown Melvaine Dobyns, of Cambridge
(A B Illinois College, 1935, M.D. Johns Hopkins Univer-
sity 1939, M.S. [in surgery] University of Minnesota 1944),
research fellow in surgery, Vincent Paul Dole, Jr., of Brook-
line (A B Stanford University 1934, M.D. Harvard Uni-
versity 1939), research fellow in medicine, Jack McCallum
Evans, of Buffalo, New York (A B Denison University
1935, M.D. University of Buffalo 1939), research fellow in
medicine, Russell Sylvester Fisher, of Alexandria, Virginia
(S B Georgia School of Technology 1937, M.D. Medical
College of Virginia 1942), research fellow in legal medicine,
Joseph Michael Foley, of Dorchester (A B Holy Cross
College 1937, M.D. Harvard University 1941), assistant
in neurology, Dan Hertz Funkenstein, of Jacksonville,
Florida (S B University of Georgia 1930, M.D. Tulane
University 1934), assistant in psychiatry, Watkins Proctor
Harvey, of Lynchburg, Virginia (A B Lynchburg College
1939, M.D. Duke University 1943), research fellow in medi-
cine, Paul Henry Harwood, Jr., of Chestnut Hill (A B
Princeton University 1935, M.D. Harvard University 1939),
assistant in psychiatry, Lester Lee Hasenbush, of Boston
(S B University of Chicago 1934, M.D. Johns Hopkins
University 1938), instructor in psychiatry, Marjone Hayes,
of Princeton, New Jersey (A B Vassar College 1937, M.D.
Johns Hopkins University 1942), assistant in psychiatry,
N. Paul Isbell, of Denver, Colorado (A B University of
Denver 1926, M.D. University of Colorado 1930), research
fellow in pathology, Herbert Jaffe of Brookline (S B Mas-
sachusetts Institute of Technology 1939, Ph.D. Massachu-
setts Institute of Technology 1943), research fellow in
medicine, Nathaniel Kengsberg, of New Haven, Connec-
ticut (A B Wesleyan University 1934, M.A. Wesleyan
University 1935, M.D. Yale University 1939), assistant in
surgery, John Albert Kneipp, of Washington, D.C. (A B
Duke University 1937, M.D. Duke University 1943), re-
search fellow in psychiatry, John Junior Kneisel, of Pelham
Manor, New York (M.D. Harvard University 1938), as-
sistant in surgery, Bernard Koechlin, of Basel, Switzerland
(Sc.D. University of Basel 1943), research fellow in physical
chemistry, Israel Kopp, of Dorchester (M.D. Tufts College
1927), research fellow in psychiatry, Francis Robert Lane,
of Somerville, Massachusetts (A B Harvard University
1940, M.D. Harvard University 1943), assistant in ob-
stetrics, Angelo Lapi, of Forty Fort, Pennsylvania (M.D.
University of Buffalo 1937) research fellow in legal medicine,
Henri Louis Marie Le Brignand, of Paris, France (B S. Uni-
versity of Paris 1931, M.D. Paris Medical School 1941),
research fellow in surgery, Julius Levine, of Dorchester
(M.D. Tufts College 1929), assistant in psychiatry, Mao-
chih Li, of Peiping, China (M.B. Medical School of Peiping
University 1929) research fellow in physiology, Rene Albert
Stephan Maurice Lontie, of Louvain, Belgium (D.Sc. Chim.
University of Louvain 1942), research fellow in physical
chemistry, Robert Alvan MacCready, of Melrose (S B
Dartmouth College 1925, M.D. Harvard University 1932),
instructor in bacteriology and immunology, Charles Alexan-
der MacGregor of Rumford, Maine (A B Colby College
1938, M.D. Harvard University 1942), assistant in sur-
gery, Nicholas Henry Martin, of Newcastle upon Tyne, Eng-
land (B S. Durham 1928, B.A. Oxford University 1933,
M.A., B.M., B.Ch. Oxford University 1937, M.R.C.P. Lon-
don University 1939), research fellow in pediatrics, Henry
Harcourt Waters Miles, of New Orleans Louisiana (S B
Tulane University 1936, M.D. Tulane University 1939),
research fellow in psychiatry, John Pervis Milnor, Jr.,
of Memphis, Tennessee (S B Yale University 1940, M.D.
University of Tennessee, College of Medicine 1942), re-
search fellow in medicine, Naum Mittelman, of Buenos
Aires, Argentina (Ph.D. Buenos Aires University 1942)
research fellow in physical chemistry, Herbert Roy Morgan,
of Riverside, California (A B University of California
1936, A.M. University of California 1933, M.D. Harvard
University 1942), research fellow in medicine, Thomas
Lynch Murphy, of Salisbury, North Carolina (A B Uni-
versity of North Carolina 1940, M.D. Harvard Univer-
sity 1943), research fellow in medicine, Roderick Murray,
of Wollaston (B S. University of Witwatersrand 1930, M.Sc.
University of South Africa 1931, M.D. Harvard Univer-

sity 1941), research fellow in medicine, Bo Norberg, of Stockholm, Sweden (M D Karolinska Institutet, Stockholm, 1942) research fellow in physical chemistry, Herbert William Park, III, of Greensboro, North Carolina (S B University of North Carolina 1944, M D Duke University 1945), research fellow in physiology, Walter Pick, of Wingham, Connecticut (M D Harvard University 1942), research fellow in pediatrics, Hele Sinclair Pittman, of Cambridge (A B Smith College 1921, M D Johns Hopkins University 1927), instructor in medicine, Sam Madison Powell, of Waco, Texas (S B University of the South 1934, M D Tulane University 1938), assistant in pediatrics, Charles Edward Rath, Jr., of Cleveland, Ohio (A B College of Wooster, 1940, M D Western Reserve University School of Medicine 1943), research fellow in medicine, Charles Washington Robertson, of Boston (A B Syracuse University 1935, M D Syracuse University 1939), assistant in surgery, Robert Rustigan, of Medford (S B Massachusetts State College 1938, S B Brown University 1940, Ph D Brown University 1943), research fellow in bacteriology and immunology, Harold Scheraga, of Brooklyn, New York (S B College of the City of New York 1941, A M Duke University 1942, Ph D Duke University 1946), research fellow in physical chemistry, Arnold Segel, of Cambridge (A B Harvard University 1932, M D Harvard University 1936), assistant in surgery, Nils Bengt Skanse, of Upsala, Sweden (M D University of Upsala 1945) research fellow in medicine, Lloyd Hollingsworth Smith, Jr., of Easley, South Carolina (A B Washington and Lee University 1944, medical student at Harvard from January 1944 to present) research fellow in physiology, Armando Soto-Rivera, of Caracas, Venezuela, South America (D M University Central de Venezuela 1943), research fellow in physiology, Herbert Carl Stoerk, of New York, New York (M D University of Vienna 1938) instructor in bacteriology and immunology, Melvin Irving Sturnick, of Allston (A B Harvard University 1935, M D Tufts College 1939), assistant in medicine, Yale Jerome Topper, of Cambridge (S B Northwestern University 1942, A M Harvard University 1943, Ph D Harvard University 1946), research fellow in biological chemistry, George Loughlin Tully, Jr., of West Newton (A B Boston College, 1941, M D Tufts College 1944), assistant in obstetrics, John Wily Garrett Tuthill, of Evanston, Illinois (A B Princeton University 1940, M D Harvard University 1943), research fellow in medicine, Bert Lester Vallee, of Brookline, Massachusetts (M D New York University 1943), research fellow in medicine, William Rhoads Waddell, of Tucson, Arizona (S B University of Arizona 1940, M D Harvard University 1943), research fellow in legal medicine, Roscoe Legrand Wall Jr., of Winston-Salem, North Carolina (S B Wake Forest 1936, S B in medicine Wake Forest 1938, M D Jefferson Medical College 1940), assistant in obstetrics, Hans Heugh Wandall, of Copenhagen, Denmark (A B Oestere Borgerdydskole, Copenhagen, 1933, M D University of Copenhagen 1940), research fellow in surgery, George Wingate Waring, Jr., of Columbia, South Carolina (S B University of South Carolina 1940, M D Johns Hopkins University 1943), assistant in pediatrics, Stanford Wessler of Albany, New York (A B Harvard University 1938 M D New York University 1942), research fellow in medicine, LeMoyne White of Walpole, New Hampshire (A B Harvard University 1936, M D Harvard University 1940), assistant in psychiatry, Joan Hilma Whittaker, of Peterborough Ontario (B S McGill University 1938) research fellow in obstetrics, James Paul Whittemore, of Somerville Massachusetts (A B Holy Cross College 1942, M D Harvard University 1945), assistant in pediatrics, and Norman Zamcheck, of Swampscott (A B Harvard University 1939, M D Harvard University 1943), research fellow in legal medicine

Although I do not own a single share of stock in any insurance company of any type, I cannot refrain from remarking that a profession which has always depended for a good part of its income (and still does) on private insurance cannot be exhibiting a narrow outlook if it adopts this proposal.

The principal contention of the letter accompanying the questionnaire is that insurance companies are in business to make money. In reply to that I would say that so are we all and it behooves physicians to encourage those who provide them with their means of subsistence to continue doing so.

I personally would not subscribe to it and on general principles I am opposed to any inconsistency which publicly places the Society on record as in favor of freedom of choice for itself but in private indorses the opposite for others.

Let us live and let live if we expect to merit the respect that we assume to be our prerogative.

HENRY G. ARMITAGE, MD

119 Emerson Street
Haverhill, Massachusetts

BOOKS RECEIVED

The receipt of the following books is acknowledged and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Fractures and Orthopaedic Surgery for Nurses and Masseuses. By Arthur Naylor, Ch M, M B, M Sc, FRCS (Eng), FRCS (Edin), resident surgical officer, Westwood E.M.S. Hospital, Bradford, examiner in surgery, General Nursing Council, and medical officer in charge, Rehabilitation Department, Westwood E.M.S. Hospital. With a foreword by Ernest Finch, M D, M S (Lond), FRCS (Eng), professor of surgery, University of Sheffield. 8° cloth, 284 pp., with 243 illustrations. Baltimore: The Williams and Wilkins Company, 1945. \$5.00.

This book is written with the objective of showing nurses how the principles of general surgery are applied to orthopedic surgery and is intended as a supplement to lectures on surgery.

Treatment in General Practice. By Harry Beckman, M D, professor of pharmacology, Marquette University School of Medicine, Milwaukee, Wisconsin. Fifth edition, reset 8° cloth, 1070 pp., illustrated. Philadelphia and London: W. B. Saunders Company, 1945. \$10.00.

Dr Beckman has thoroughly revised this fifth edition of an authoritative text in the light of the numerous developments in therapeutics during the last four years. Many subjects have been completely rewritten, and a large number are included for the first time. Many of these subjects have emanated from military experience, including anaphylactic, cardiogenic, crush, primary, secondary and surgical shock, air sickness, blast syndrome, chemical burns, gas gangrene and various types of poisoning. The text has been completely reset. This book should prove of value to all practicing physicians and should be in all medical reference collections.

The Intervertebral Disc. With special reference to rupture of the annulus fibrosus with herniation of the nucleus pulposus. By F. Keith Bradford, M D, and R. Glenn Spurling, M D. Second edition. 8° cloth. 192 pp., and 70 illustrations. Springfield, Illinois: Charles C. Thomas, 1945. \$4.00.

The text of this monograph has been revised in accordance with the experience gained during the last four years. The new technique for myelography and the use of Pantopaque are described. Thirteen full case reports illustrating important points conclude the clinical part of the work. A bibliography of three hundred and seven references is appended to the text. The book is printed with good type on good paper in the usual Thomas manner. This monograph should be in all medical reference collections and the libraries of surgeons who are interested in rupture of the intervertebral disk.

(Notices on page vii)

CORRESPONDENCE

MALPRACTICE INSURANCE

To the Editor: In this week's mail I received a questionnaire from the Massachusetts Medical Society on the subject of a group plan for insurance against malpractice to be sponsored by the Society.

SYMPOSIUM ON GASTROINTESTINAL BLEEDING*

DIAGNOSTIC AND THERAPEUTIC CONSIDERATIONS OF GASTROINTESTINAL BLEEDING

CHESTER M. JONES, M.D.†

BOSTON

ANY consideration of bleeding from the gastrointestinal tract holds the immediate implication that the problem may be either medical or surgical. This is of primary importance and must never be forgotten, either in the discussion of the general problem or in the making of decisions in the individual case. Because of the possible necessity of surgical intervention, gastrointestinal hemorrhage must invariably be considered from three distinct points of view. It must be thought of in terms of the actual site of the bleeding, which implies the necessity for accurate diagnosis whenever possible. The mechanism underlying the hemorrhage must also be carefully evaluated so that proper therapeutic measures may be decided on. The third consideration is the condition of the patient who is bleeding. Even before diagnostic or definitive therapeutic measures are undertaken, a decision must be made regarding the urgency of the situation in terms of shock and circulatory collapse.

A clear differentiation is needed between abrupt hemorrhage of shock proportions and minor oozing that, in the long run, may lead to more or less serious grades of anemia but is not an immediate threat to life. In major acute episodes the immediate concern is the safety of the patient. Even under the pressure of exsanguinating hemorrhage, however, selected diagnostic procedures are indicated if successful definitive measures are to be carried out. At the same time, a knowledge of the hazards involved is essential in arriving at a final decision concerning therapy, whether medical or surgical.

Any attempt to classify digestive-tract bleeding on the basis of the site of the lesion must be founded on a knowledge of anatomic and pathologic abnormalities encountered at various levels of the alimentary canal. This can be divided roughly into

three segments from the pharynx to the ligament of Treitz, from the ligament of Treitz to the ileocecal valve and from the ileocecal valve to the anus. A fourth possible subdivision includes the anal canal only.

In the upper segment — namely, the esophagus, stomach and duodenum — bleeding is usually associated with the vomiting of coffee-grounds material, inky-black fluid or frank blood. Even with esophageal bleeding, however, blood may not be vomited, and hemorrhage may be suspected only because of tarry stools. Melena is the rule in upper gastrointestinal-tract bleeding, but it must not be forgotten that feces containing currant-jelly-like, deep-reddish material may be encountered if the hemorrhage is brisk and the peristaltic rate rapid.

Esophageal bleeding is due either to varices or to cancer in most cases. Bleeding infrequently occurs from varices that are located in the fundus of the stomach rather than in the esophagus. Bleeding from esophageal ulcer can occur, but it is rare.

Gastroduodenal hemorrhage is usually due to peptic ulcers, the great majority of which are located in the first portion of the duodenum. Benign ulcers that bleed may occur, however, anywhere from the cardiac end of the stomach to the ligament of Treitz, and can be identified only by careful roentgenologic studies. Cancer of the stomach causes massive hemorrhage only occasionally, but it can do so. Less frequent causes of bleeding from the stomach are erosive gastritis, generalized or localized as in a diaphragmatic hernia, benign tumors that have become ulcerated and rare tumors, such as leiomyosarcomas, fibromas and neuromas. Carcinoma of the duodenum is extremely infrequent, but does occur and may cause bleeding. Duodenal leiomyosarcomas are more frequent and may underlie a serious anemia or may cause a fairly brisk hemorrhage.

It should be emphasized that gastritis alone is occasionally the source of an exsanguinating loss of

*The three papers comprising this symposium were presented at the annual meeting of the Massachusetts Medical Society, Boston, May 23, 1946.

†Clinical professor of medicine, Harvard Medical School physician, Massachusetts General Hospital.

sity 1941), research fellow in medicine, Bo Norberg, of Stockholm, Sweden (M.D. Karolinska Institutet, Stockholm, 1942) research fellow in physical chemistry, Herbert William Park, III, of Greensboro, North Carolina (S.B. University of North Carolina 1944, M.D. Duke University 1945), research fellow in physiology, Walter Pick, of Wingham, Connecticut (M.D. Harvard University 1942), research fellow in pediatrics, Hele Sinclair Pittman, of Cambridge (A.B. Smith College 1921, M.D. Johns Hopkins University 1927), instructor in medicine, Sam Madison Powell, of Waco, Texas (S.B. University of the South 1934, M.D. Tulane University 1938), assistant in pediatrics, Charles Edward Rath, Jr., of Cleveland, Ohio (A.B. College of Wooster 1940, M.D. Western Reserve University School of Medicine 1943), research fellow in medicine, Charles Washington Robertson, of Boston (A.B. Syracuse University 1935, M.D. Syracuse University 1939), assistant in surgery, Robert Rustigian, of Medford (S.B. Massachusetts State College 1938, S.M. Brown University 1940, Ph.D. Brown University 1943), research fellow in bacteriology and immunology, Harold Scheraga, of Brooklyn, New York (S.B. College of the City of New York 1941, A.M. Duke University 1942, Ph.D. Duke University 1946), research fellow in physical chemistry, Arnold Segel, of Cambridge (A.B. Harvard University 1932, M.D. Harvard University 1936), assistant in surgery, Nils Bengt Skanse, of Upsala, Sweden (M.D. University of Upsala 1945) research fellow in medicine, Lloyd Hollingsworth Smith, Jr., of Easley, South Carolina (A.B. Washington and Lee University 1944, medical student at Harvard from January 1944 to present) research fellow in physiology, Armando Soto-Rivera, of Caracas, Venezuela, South America (D.M. University Central de Venezuela 1943), research fellow in physiology, Herbert Carl Stoerk, of New York, New York (M.D. University of Vienna 1938) instructor in bacteriology and immunology, Melvin Irving Sturmick, of Allston (A.B. Harvard University 1935, M.D. Tufts College 1939), assistant in medicine, Yale Jerome Topper, of Cambridge (S.B. Northwestern University 1942, M.M. Harvard University 1943, Ph.D. Harvard University 1946), research fellow in biological chemistry, George Loughlin Tully, Jr., of West Newton (A.B. Boston College, 1941, M.D. Tufts College 1944), assistant in obstetrics, John Wily Garrett Tutthill, of Evanston, Illinois (A.B. Princeton University 1940, M.D. Harvard University 1943), research fellow in medicine, Bert Lester Vallee, of Brookline, Massachusetts (M.D. New York University 1941), research fellow in medicine, William Rhoads Waddell, of Tucson, Arizona (S.B. University of Arizona 1940, M.D. Harvard University 1943), research fellow in legal medicine, Roscoe Legrand Wall, Jr., of Winston-Salem, North Carolina (S.B. Wake Forest 1936, S.B. in medicine Wake Forest 1938, M.D. Jefferson Medical College 1940), assistant in obstetrics, Hans Heugh Wandall, of Copenhagen, Denmark (A.B. Oestere Borgerdydskole, Copenhagen, 1933, M.D. University of Copenhagen 1940), research fellow in surgery, George Wingate Waring, Jr., of Columbia, South Carolina (S.B. University of South Carolina 1940, M.D. Johns Hopkins University 1943), assistant in pediatrics, Stanford Wessler of Albany, New York (A.B. Harvard University 1938, M.D. New York University 1942), research fellow in medicine, LeMoyne White of Walpole, New Hampshire (A.B. Harvard University 1936, M.D. Harvard University 1940), assistant in psychiatry, Joan Hilma Whittaker, of Peterborough, Ontario (B.S. McGill University 1938) research fellow in obstetrics, James Paul Whittemore, of Somerville, Massachusetts (A.B. Holy Cross College 1942, M.D. Harvard University 1945), assistant in pediatrics, and Norman Zamcheck, of Swampscott (A.B. Harvard University 1939, M.D. Harvard University 1943), research fellow in legal medicine

Although I do not own a single share of stock in any insurance company of any type, I cannot refrain from remarking that a profession which has always depended for a part of its income (and still does) on private insurance cannot be exhibiting a narrow outlook if it adopts this proposal.

The principal contention of the letter accompanying the questionnaire is that insurance companies are in business to make money. In reply to that I would say that so are we, and it behooves physicians to encourage those who provide them with their means of subsistence to continue doing so.

I personally would not subscribe to it and on general principles I am opposed to any inconsistency which places the Society on record as in favor of freedom of choice for itself but in private indorses the opposite for others.

Let us live and let live if we expect to merit the respect that we assume to be our prerogative.

Haverhill, Massachusetts

BOOKS RECEIVED

The receipt of the following books is acknowledged and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Fractures and Orthopaedic Surgery for Nurses and Masters. By Arthur Naylor, Ch.M., M.B., M.Sc., F.R.C.S. (Eng.), F.R.C.S. (Edin.), resident surgical officer, Westwood E.M. Hospital, Bradford, examiner in surgery, General Nursing Council, and medical officer in charge, Rehabilitation Department, Westwood E.M.S. Hospital. With a foreword by Ernest Finch, M.D., M.S. (Lond.), F.R.C.S. (Eng.), professor of surgery, University of Sheffield. 8° cloth, 2 pp., with 243 illustrations. Baltimore: The Williams & Wilkins Company, 1945. \$5.00.

This book is written with the objective of showing nurses how the principles of general surgery are applied to orthopedic surgery and is intended as a supplement to lectures on surgery.

Treatment in General Practice. By Harry Beckman, M.D., professor of pharmacology, Marquette University School of Medicine, Milwaukee, Wisconsin. Fifth edition, reset. 8° cloth, 1070 pp., illustrated. Philadelphia and London: W.B. Saunders Company, 1945. \$10.00.

Dr. Beckman has thoroughly revised this fifth edition of an authoritative text in the light of the numerous developments in therapeutics during the last four years. Many subjects have been completely rewritten, and a large number are included for the first time. Many of these subjects have emanated from military experience, including anaphylactic, cardiogenic, crush, primary, secondary, and surgical shock, air sickness, blast syndrome, chemical burn, gas gangrene and various types of poisoning. The text has been completely reset. This book should prove of value to all practicing physicians and should be in all medical reference collections.

The Intervertebral Disc With special reference to rupture of the annulus fibrosus with herniation of the nucleus pulposus. By F. Keith Bradford, M.D., and R. Glenn Spurling, M.D. Second edition. 8° cloth, 192 pp., and 70 illustrations. Springfield, Illinois: Charles C. Thomas, 1945. \$4.00.

The text of this monograph has been revised in accordance with the experience gained during the last four years. The new technique for myelography and the use of Pantopaque are described. Thirteen full case reports, illustrating important points, conclude the clinical part of the work. A bibliography of three hundred and seven references is appended to the text. The book is printed with good type on good paper in the usual Thomas manner. This monograph should be in all medical reference collections and the libraries of surgeons who are interested in rupture of the intervertebral disk.

(Notice on page viii)

CORRESPONDENCE

MALPRACTICE INSURANCE

To the Editor: In this week's mail I received a questionnaire from the Massachusetts Medical Society on the subject of a group plan for insurance against malpractice to be sponsored by the Society.

alimentary canal Specific toxic agents such as arsenite and radium may cause bloody diarrhea as a result of damage to the capillaries or bone marrow Not infrequently, similar symptoms occur in uremia, but only as a terminal event

It is thus obvious that a proper evaluation of gastrointestinal bleeding must include exact knowledge of the site of loss and, in addition, an understanding of the mechanism involved Without such an evaluation, therapeutic measures cannot be properly carried out It may be added that failure to obtain sufficient information to cover both requirements constitutes a failure of medical management and cannot be condoned Furthermore, it is essential to stress the fact that obvious sources of bleeding may not provide the actual explanation for hemorrhagic episodes Much too often the demonstration of hemorrhoids or anal fissures is accepted as a satisfactory explanation of rectal bleeding when the true cause is a carcinoma of the bowel or a serious ulcerative process

To obtain adequate information regarding the source and nature of gastrointestinal bleeding, carefully selected diagnostic procedures must be carried out If the hemorrhage is a massive one and shock is present or imminent, such measures must of necessity be brief and to the point They must not interfere with the immediate treatment needed for combating acute blood loss Blood volume must be restored at once by transfusions of whole blood, but this must not be administered so rapidly as to cause a sharp rise in blood pressure Gravity-drip, regulated transfusions are the measure of choice, and should be used until shock is controlled Plasma, which is of much less value than whole blood, should be used only when blood is unavailable An important reason for avoiding the use of pooled plasma, in addition to the fact that it does not replace hemoglobin and prothrombin, is that it carries a definite risk of transmitting the virus of infectious hepatitis Physiologic saline solution should be used only as a temporary expedient until whole blood can be obtained In the presence of protein or albumin lack, such as that occurring in depleted patients or in serious hepatic disease, the use of saline solution may precipitate the appearance of pulmonary edema or generalized tissue edema

During the period of shock therapy, certain valuable diagnostic information can be obtained A history of previous ulcer may be elicited from the family or friends or from the patient Evidence of emaciation may suggest the presence of cancer Spider angiomas may lead to an immediate diagnosis of portal hypertension, with esophageal or gastric varices The presence of jaundice may incriminate the liver Light percussion may demonstrate splenic enlargement and lead to a similar conclusion Inspection may reveal an abdominal mass necessitating an obvious diagnosis of cancer Abdominal palpation must be done with caution, if

at all, but may yield diagnostic information A careful digital examination may reveal a tumor mass in the rectum, immediately indicating the diagnosis

As soon as the danger of shock has been successfully met or it is apparent that major bleeding is not present, more intensive diagnostic measures can be instituted These should be carried out in the following order a searching history, a thorough physical examination, careful roentgenologic studies, — discussed and planned according to the findings of the history and physical examination, — endoscopy and a few laboratory tests A meticulous history alone may indicate the segment to be studied even if a positive diagnosis cannot be made Substernal epigastric symptoms imply upper-segment disease, periumbilical pain suggests the small intestine as the source of bleeding, discomfort in the right lower quadrant should lead to examination of the ileocecal region, and hypogastric distress suggests colonic disease Positive physical findings may be diagnostic, but they are often notable for their absence A palpable mass means cancer until proved otherwise by direct inspection In most cases, the indicated roentgenologic studies, without manipulation, should be carried out within twenty-four to forty-eight hours of the occurrence of massive bleeding

Gastroscopy, esophagoscopy and sigmoidoscopy should be postponed until active bleeding ceases The indications for their use are clear In the absence of definite roentgenologic findings, or when supplemental evidence regarding the nature of the bleeding lesion is desirable, endoscopic examination should be performed as soon after major bleeding has ceased as it can safely be done Sigmoidoscopic examination should precede roentgenologic study It may give more accurate information than a barium enema — in mild ulcerative colitis, for example Similarly, it may reveal a polyp or a cancer that is difficult to demonstrate roentgenologically In the presence of hemorrhoids or an anal fissure, sigmoidoscopy is essential to rule out a more serious source of bleeding at a higher level With bleeding obviously arising from the lower digestive tract, a negative sigmoidoscopy immediately provides the proper impetus for a serious roentgenologic study of the upper colon and terminal ileum

Gastroscopy, in experienced hands, is the only way to demonstrate an active gastritis that is responsible for upper-segment hemorrhage Esophagoscopy is of use primarily in obtaining biopsy material from a suspected esophageal growth It should not be used to visualize varices, which are almost always readily shown by proper roentgenologic studies

Laboratory tests are of much less diagnostic importance than the measures discussed above in determining the source or nature of gastrointestinal bleeding The finding of histamine achlorhydria in the presence of a demonstrated gastric lesion is of

blood. It is also essential to remember that massive hemorrhage from ulcer is frequently unassociated with pain.

In the midsegment — the jejunum and ileum — massive hemorrhage is rather rare, but anemia from chronic loss of relatively small amounts of blood is not infrequent. Hematemesis does not occur from lesions below the ligament of Treitz, except in the presence of frank obstruction with fecal vomiting, or in association with an ulcerated lesion near the stoma of a gastroenterostomy. Dependent on the peristaltic rate, bleeding from the midsegment may result in either tarry stools or fresh, blood-stained feces.

Acute bleeding may result from frank ulceration, such as that encountered in typhoid fever, or from a single ulcer, notably that associated with a Meckel's diverticulum, which is usually, but not invariably, seen in children and young adults. Tumors, unless pedunculated and therefore subject to torsion, do not, as a rule, cause massive bleeding. Rather, they result in a gradually progressive anemia due to ulceration and oozing. Carcinomas, leiomyosarcomas, lymphomas and benign polypoid tumors, such as simple adenomas and lipomas, cause bleeding that may or may not be associated with the clinical picture of intussusception. With modern methods of roentgenologic examination, the site of the bleeding in the small intestine is often demonstrated if its approximate location is suspected. Other sources of moderate bleeding in this portion of the bowel are the granulomatous processes, notably tuberculosis and regional enteritis, both of which tend to be located in the vicinity of the ileocecal valve. Acute infectious processes, such as food poisoning and gastroenteritis due to what is popularly known as "intestinal gripe," may cause moderate bleeding from the small intestine.

Bleeding in the colon, which may be due to a wide variety of conditions, is demonstrated by the passage of varying amounts of fresh or slightly altered blood in the stools. Cancer must be suspected first, last and always in the presence of colonic bleeding. Until it is eliminated no other diagnosis should be considered. Carcinoma of the colon may cause gross, shock-producing hemorrhage, but as a rule effects a more chronic blood loss resulting in an anemia that may be serious. Other tumors are the source of intermittent fresh bleeding. Of these, in the absence of signs of serious disease, the adenomatous polyp, which is always potentially cancerous, should be the first suspect.

If carcinoma and adenoma can be ruled out, colonic bleeding should suggest the possibility of one of the various forms of ulcerative colitis. If the onset is abrupt, amebic and bacillary dysentery must be eliminated by appropriate diagnostic measures. Tuberculous colitis and idiopathic ulcerative colitis are usually more insidious in onset and more chronic in their clinical manifestations

but, like the dysenteries, are accompanied diarrhea.

An important cause of serious colonic bleed may be the end result of damage to the b secondary to heavy irradiation of pelvic tun. Rarely, bright-red blood may be passed by rec from areas of diverticulitis or in the presenc mucous colitis. Such a possibility should neve considered until all other sources of bleeding h been eliminated, and even then it should be accep only with extreme skepticism.

I have enumerated many of the possible sou of gastrointestinal hemorrhage on the basis o strict anatomic or pathologic location. It is equ necessary to visualize the type of mechanism involved in the hemorrhage. This is particularly vi in arriving at the details of therapeutic managem involved in any given case. For example, the ble ing from a peptic ulcer is essentially arterial a therefore has a graver prognosis at the age of six than at thirty, owing to the fact that the arteri are less elastic, contract less well and, in additio may carry a high systolic pressure. Bleeding fro varices, on the other hand, is from a thin-walle relatively atonic vessel that is easily traumatize and has little contractility but has great possibilit of thrombosis and obliteration by clot formatio. The hemorrhage secondary to a mesenteric-arter thrombosis carries with it the added threat of ga grene of the bowel and therefore the possible neces sity of emergency surgery.

Capillary bleeding may occur over a large enoug area to provide an immediate threat to life, al though, as a rule, it is of lesser magnitude. The bleeding from gastritis, either diffuse or localized, and that encountered in idiopathic ulcerative colitis are usually of capillary origin. Similarly, in bacillary dysentery, bleeding is the result of tiny, superfical mucosal erosions involving capillary loops. In diverticulitis and so-called "mucous colitis," the infrequent episode of bleeding is probably due to a local inflammatory process with involvement of a small vessel. In hemorrhage secondary to post radiation lesions of the sigmoid or ileum, the bleed ing comes from telangiectatic areas similar to those noted in the skin following x-ray burns but because of the larger vessels involved, may be of greater degree than that usually noted in capillary oozing and may require local surgical resection.

Significant hemorrhage, essentially of capillary origin, may be due to general hemorrhagic disturbances associated with the thrombocytopenia encountered in the leukemias and bone-marrow aplasias, or with the prothrombin lack associated with serious hepatic disease or chronic diarrhea. Vitamin C deficiency may provide the basis for blood loss from the digestive tract from capillary oozing. Similarly, serious capillary bleeding may be due to hemophilia, but this is only a manifestation of a general physiologic disorder affecting more than the

imentary canal. Specific toxic agents such as acetone and radium may cause bloody diarrhea as a result of damage to the capillaries or bone marrow. Not infrequently, similar symptoms occur in uremia, but only as a terminal event.

It is thus obvious that a proper evaluation of gastrointestinal bleeding must include exact knowledge of the site of blood loss and, in addition, an understanding of the mechanism involved. Without such an evaluation, therapeutic measures cannot be properly carried out. It may be added that failure to obtain sufficient information to cover both requirements constitutes a failure of medical management and cannot be condoned. Furthermore, it is essential to stress the fact that obvious sources of bleeding may not provide the actual explanation for hemorrhagic episodes. Much too often the demonstration of hemorrhoids or anal fissures is accepted as a satisfactory explanation of rectal bleeding when the true cause is a carcinoma of the bowel or a chronic ulcerative process.

To obtain adequate information regarding the source and nature of gastrointestinal bleeding, carefully selected diagnostic procedures must be carried out. If the hemorrhage is a massive one and shock is present or imminent, such measures must of necessity be brief and to the point. They must not interfere with the immediate treatment needed for combating acute blood loss. Blood volume must be restored at once by transfusions of whole blood, but this must not be administered so rapidly as to cause a sharp rise in blood pressure. Gravity-drip, regulated transfusions are the measure of choice, and should be used until shock is controlled. Plasma, which is of much less value than whole blood, should be used only when blood is unavailable. An important reason for avoiding the use of pooled plasma, in addition to the fact that it does not replace hemoglobin and prothrombin, is that it carries a definite risk of transmitting the virus of infectious hepatitis. Physiologic saline solution should be used only as a temporary expedient until whole blood can be obtained. In the presence of protein or albumin lack, such as that occurring in depleted patients or in serious hepatic disease, the use of saline solution may precipitate the appearance of pulmonary edema or generalized tissue edema.

During the period of shock therapy, certain valuable diagnostic information can be obtained. A history of previous ulcer may be elicited from the family or friends or from the patient. Evidence of emaciation may suggest the presence of cancer. Spider angiomas may lead to an immediate diagnosis of portal hypertension, with esophageal or gastric varices. The presence of jaundice may incriminate the liver. Light percussion may demonstrate splenic enlargement and lead to a similar conclusion. Inspection may reveal an abdominal mass necessitating an obvious diagnosis of cancer. Abdominal palpation must be done with caution, if

at all, but may yield diagnostic information. A careful digital examination may reveal a tumor mass in the rectum, immediately indicating the diagnosis.

As soon as the danger of shock has been successfully met or it is apparent that major bleeding is not present, more intensive diagnostic measures can be instituted. These should be carried out in the following order: a searching history, a thorough physical examination, careful roentgenologic studies, — discussed and planned according to the findings of the history and physical examination, — endoscopy and a few laboratory tests. A meticulous history alone may indicate the segment to be studied even if a positive diagnosis cannot be made. Substernal epigastric symptoms imply upper-segment disease, periumbilical pain suggests the small intestine as the source of bleeding, discomfort in the right lower quadrant should lead to examination of the ileocecal region, and hypogastric distress suggests colonic disease. Positive physical findings may be diagnostic, but they are often notable for their absence. A palpable mass means cancer until proved otherwise by direct inspection. In most cases, the indicated roentgenologic studies, without manipulation, should be carried out within twenty-four to forty-eight hours of the occurrence of massive bleeding.

Gastroscopy, esophagoscopy and sigmoidoscopy should be postponed until active bleeding ceases. The indications for their use are clear. In the absence of definite roentgenologic findings, or when supplemental evidence regarding the nature of the bleeding lesion is desirable, endoscopic examination should be performed as soon after major bleeding has ceased as it can safely be done. Sigmoidoscopic examination should precede roentgenologic study. It may give more accurate information than a barium enema — in mild ulcerative colitis, for example. Similarly, it may reveal a polyp or a cancer that is difficult to demonstrate roentgenologically. In the presence of hemorrhoids or an anal fissure, sigmoidoscopy is essential to rule out a more serious source of bleeding at a higher level. With bleeding obviously arising from the lower digestive tract, a negative sigmoidoscopy immediately provides the proper impetus for a serious roentgenologic study of the upper colon and terminal ileum.

Gastroscopy, in experienced hands, is the only way to demonstrate an active gastritis that is responsible for upper-segment hemorrhage. Esophagoscopy is of use primarily in obtaining biopsy material from a suspected esophageal growth. It should not be used to visualize varices, which are almost always readily shown by proper roentgenologic studies.

Laboratory tests are of much less diagnostic importance than the measures discussed above in determining the source or nature of gastrointestinal bleeding. The finding of histamine achlorhydria in the presence of a demonstrated gastric lesion is of

value because it implies cancer as the underlying cause. Otherwise, gastric analysis is a needless procedure in the problem under discussion. When bleeding is due to a blood dyscrasia, such as thrombocytopenia, proper blood studies are obviously diagnostic. A prothrombin lack can be demonstrated only by a prothrombin determination, but decision regarding the underlying cause of blood loss is usually made by simple clinical observation, which is then confirmed by the appropriate laboratory test. In the main, laboratory findings are of aid only in demonstrating and measuring the effects of hemorrhage and in thus giving direction and timing to the proper treatment to correct blood loss.

The therapy of gastrointestinal hemorrhage is twofold. Immediate treatment has already been mentioned. It should be straightforward, adequate and continued until the pressing hazard of shock has been controlled, or until it is obvious that bleeding is not subsiding. In the latter event, a decision must be made for emergency surgical intervention. Subsequent therapeutic measures must be equally straightforward and directed toward obtaining medical control of the cause of bleeding or surgical removal of its source. When cancer is suspected or proved, radical surgical procedures must be instituted as soon as proper preoperative preparations to combat anemia, depletion, specific vitamin lack and the like have been carried out. In the presence of a proved peptic ulcer not requiring emergency surgery, simple feeding measures should be started early, and moderate sedation achieved. In my opinion, morphine should not be used because of its tendency to cause nausea and abnormal duodenal spasm, it is not a sedative, and barbiturates are more satisfactory. The current suggestion for the feeding of amino acid preparations may be useful in extremely malnourished patients, but simple, less distasteful feedings are usually preferable. Antacids may be helpful, and atropine may also be used to advantage either by mouth or parenterally. Iron should be avoided until all ulcer activity has ceased, because of its frequent irritating effect on the gastrointestinal tract. Transfusions, once the hemoglobin is at a safe level, are not needed and are probably inadvisable. After the bleeding episode has been

successfully managed, proper elective surgery is usually indicated if the hemorrhage has been major one. There are occasional exceptions to such a decision.

In bleeding from esophageal varices, feeding should be delayed because of the danger of further trauma to a ruptured varix. Because bleeding from this source is usually secondary to severe liver disease, transfusions or vitamin K or both are indicated for the additional purpose of correcting a bleeding tendency due to prothrombin lack.

Treatment of hemorrhage from gastritis is essentially the same as that from ulcer. If there has been prolonged vomiting, however, intravenous feeding must be utilized as a temporary expedient to replace fluid and electrolytes and to prevent gastric irritation. When massive bleeding occurs as a result of a local gastritis or an ulcer in a diaphragmatic hernia, medical treatment should usually be followed by elective transthoracic surgery aimed at repairing the hernia.

I shall mention only one other specific cause of bleeding — namely, ulcerative colitis. In this distressing condition, bleeding occasionally dominates the clinical picture. If intensive medical therapy does not control the blood loss in a reasonable and limited period, it is imperative that a decision be made for adequate surgical measures — ileostomy or colectomy, depending on which maneuver is indicated in the individual case.

Bleeding from direct trauma, which obviously falls into a separate category, is not considered

* * *

In this review of gastrointestinal bleeding as seen by the internist, I have tried to stress certain important points, none of which are new. Determination of the site and character of the hemorrhage — that is, exact diagnosis — is essential to proper, detailed therapeutic measures. Treatment must be directed toward immediate control of the sequelae of massive hemorrhage and subsequently toward adequate cure or management of the underlying cause. To achieve satisfactory results, the close cooperation of a well trained roentgenologist and of a competent surgeon is essential.

THE SURGICAL ASPECTS OF HEMORRHAGE FROM PEPTIC ULCER*

GEORGE J HEUER, M D†

NEW YORK CITY

A STUDY of the patients who have entered the surgical wards of the New York Hospital with serious hemorrhage from the gastrointestinal tract shows that the large majority were the victims of duodenal or gastric ulcer, whereas a minority presented a variety of other pathologic conditions. I was asked to discuss the large subject of hemorrhage from the gastrointestinal tract in its relation to surgery, but since it is obvious that I cannot cover so large a field in the short time at my disposal, I shall confine myself to the surgical aspects of hemorrhage from peptic ulcer, which, in my experience far overshadows in importance the others.

In reviewing this experience I find that of over 1800 patients with duodenal and gastric ulcer admitted to the surgical wards between September 1, 1932, and January 1, 1946, a total of 337 were admitted specifically because of serious hemorrhage. These cases have been reviewed from time to time. Holman,¹ in an analysis of the first 90 cases of serious hemorrhage, observed that 12 patients died, a mortality from hemorrhage of 13 per cent. In this group, 4 patients were in such a desperate condition that operation was never considered possible, 4 were operated on as a last resort, 4 recovered to a point where operation could have been performed but surgery was delayed, with the result that they died from a second massive hemorrhage. On the other hand, 4 patients operated on during active bleeding recovered. This experience shows that 8 patients in whom operation was not undertaken died from hemorrhage and that of 8 subjected to operation as a desperate venture, 4 recovered and 4 died — a surgical mortality of 50 per cent. Of the 74 patients who recovered from the primary hemorrhage under expectant treatment, 16 had been subjected to gastric resection at the time of the report and all had recovered.

Holman² subsequently studied 161 patients with severe hemorrhage admitted between 1932 and 1940, including the 90 referred to above. In this series there were 18 deaths during the period of active bleeding, a mortality from hemorrhage of 11 per cent. Thirteen patients died without having been subjected to surgery. Fourteen patients were operated on in the period of active bleeding, with 5 deaths — a surgical mortality of 35 per cent. Of the 134 patients who recovered from the primary hemorrhage under expectant treatment, 31 had been subjected to gastric resection at the time of the report, with 1 death — a mortality of 3 per cent.

Clifton,³ beginning where Holman left off, added 103 patients with serious hemorrhage admitted between July 1, 1940, and July 1, 1943. In this series there were 5 deaths during the period of active bleeding, a mortality from hemorrhage of less than 5 per cent. Three patients could not be brought into condition for operation and died two hours, eight hours and five days, respectively, after admission. Operation was performed in 8 cases during the period of active bleeding, with recovery in 6 and death in 2 — a surgical mortality of 25 per cent. Of the 92 patients who recovered from the primary hemorrhage, 41 had been subjected to gastric resection at the time of the report, with 2 deaths — a surgical mortality of 5 per cent.

Cooper,⁴ in a study of 73 patients with serious hemorrhage admitted since Clifton's report and covering the period from July 1, 1943, to January 1, 1946, found a total of 5 deaths, only 4 of which could be related to hemorrhage, however. This represents a mortality from hemorrhage of 5 per cent. Two patients died from hemorrhage without having been subjected to operation. Nine patients were operated on in the period of active bleeding — of whom 7 had gastric resections — with 2 deaths, a surgical mortality of 22 per cent. Of the 62 patients who recovered from the primary hemorrhage 33 were subjected to operation within four to six weeks, of whom 30 were subjected to gastric resection, 1 to a gastroenterostomy, 1 to a ligation of the gastric artery and 1 to an exploratory laparotomy. There was 1 postoperative death, an operative mortality of 3 per cent. As of January 1, 1946, there were 29 patients who had not been subjected to operation.

In summary, of 337 patients with peptic ulcer admitted to the hospital because of serious or massive hemorrhage, 27 (8 per cent) died from hemorrhage. Eighteen died without having been subjected to surgery, in the majority of cases the condition of the patient precluding, in the judgment of the surgeon, an operative procedure. Thirty-one patients were operated on in the period of active primary hemorrhage, with 9 postoperative deaths — a surgical mortality of 29 per cent. From the location of the ulcer and the source of bleeding it is probable that all 31 patients would have died had surgery not been undertaken. It thus appears that 49, or 15 per cent, of the total number of patients admitted because of severe hemorrhage were examples of fatal hemorrhage, a higher percentage than is usually appreciated.

Of the 288 patients who recovered from hemorrhage under expectant treatment, 105 were sub-

*From the Departments of Surgery, New York Hospital and Cornell University Medical College.
†Professor of surgery, Cornell University Medical College surgeon-in-chief New York Hospital.

jected to operation at the time of the reports mentioned above. The operation was, with few exceptions, a gastric resection with removal of the ulcer — and was performed usually within four to six weeks after the primary hemorrhage. There were 4 post-operative deaths, a case mortality of 4 per cent. The remaining 183 patients were discharged from the hospital to be followed in the clinic.

From the 18 patients who died without operation, in whom permission for autopsy was obtained in a high percentage of cases, from the 31 subjected to operation during the period of active bleeding and from the 105 patients operated on within four to six weeks after recovery from the hemorrhage that led to admission, a total of 154 cases, it has been learned that the location of the ulcer with reference to immediately adjacent large arteries is the determining factor in the seriousness of or fatality from hemorrhage. Without exception the duodenal ulcers with hemorrhage that was fatal or unchecked by a conservative regimen were located on the posterior duodenal wall and had eroded the pancreaticoduodenal artery or one of its major branches, if gastric, the ulcers were on the lesser curvature, eroding a large branch of the right or left gastric artery. The pathologic picture was strikingly similar in all cases: the ulcer was deep and presented a hard, fibrous base in which there was an eroded, open artery whose lumen, in some of the specimens at autopsy, was large enough to admit a matchstick. In this series the ulcer that gave rise to fatal hemorrhage, if unchecked by surgery, was located in one or the other of the two areas indicated and was usually chronic, and the hemorrhage was arterial and more frequently from a single eroded artery.

At operation performed during the period of bleeding, a conical clot temporarily stopped the bleeding from even a large eroded artery, but I have also observed how easily such a clot may be dislodged and how unlikely it is to become organized and fixed. It is not implied from these statements that hemorrhage from ulcers of the posterior wall of the duodenum or lesser curvature may not, under a medical regimen, spontaneously cease, for it is of course the size of the blood vessel eroded that is the determining factor. The ulcers with hemorrhage that was checked under a conservative regimen were in most cases located away from the two dangerous vascular areas described above or, if located in those areas, had not eroded a large artery. It is the early, acute and not deeply penetrating ulcers — those of the anterior wall of the duodenum and those of the distal portion of the lesser curvature and fundus of the stomach — that give rise to less dangerous hemorrhages.

It is evident from this experience that in any series of patients with serious hemorrhage as the primary cause of admission to the hospital, there will be two groups — a minority, in whom hemorrhage, if not surgically checked, is fatal, and a

majority, in whom hemorrhage, under expectant treatment, spontaneously ceases. In our experience the former group varied in different periods from 18 to 11 per cent of the total, averaging about 1 per cent. No doubt this percentage varies in different clinics, but it is evident from the literature that surgical clinics quite generally have a minority group of greater or lesser size to contend with.

The immediate clinical problem is accurately to differentiate the group whose hemorrhage is uncontrollable short of surgical measures and that whose hemorrhage ceases under conservative measures. The immediate surgical problem is how, in patients with uncontrollable hemorrhage, to arrange all details of a surgical procedure so as to save the greatest number of lives. A third, but not so immediate problem, is how most intelligently to care for the majority group, who have recovered from hemorrhage under expectant treatment.

The differentiation of patients whose hemorrhage is likely to prove fatal if unchecked by surgery and those in whom it ceases under a proper conservative regimen has proved extremely difficult. Patients are admitted in all stages of reaction to hemorrhage. Some are in such a desperate condition that they die in the emergency unit before they can be transferred to the wards, in spite of large or repeated small blood transfusions. Others less profoundly affected show great variations in their reactions to hemorrhage, as manifested by physical appearance, pulse rate, respiration, blood pressure, sweating, mental state, blood counts and hemoglobin determinations. It is well known that patients react differently to the loss of blood and that unless some accurate data can be obtained regarding the amount of blood vomited or passed by rectum, it may not be known on admission of the patient how large a hemorrhage has taken place. Moreover, the clinical picture presented cannot immediately reveal whether the hemorrhage is derived from an eroded pancreaticoduodenal artery and will continue, proving fatal if unchecked, or whether it is derived from an ulcer in a less dangerous location and will cease under a conservative regimen. It is a question whether one should attempt, in the early period of observation, to establish the location of the ulcer and thus clarify the situation regarding therapy. In many patients, attempts at gastroscopy are unwise and impossible, a swallow or two of barium, with observation under the fluoroscope, had tragic consequences in 3 cases, being promptly followed by a fatal secondary hemorrhage. It appears logical, in all the circumstances, to attempt to differentiate patients whose hemorrhage is likely to prove fatal and those whose hemorrhage is likely to cease spontaneously by following the early clinical course under appropriate treatment — that is, to put them to bed, to administer moderate doses of morphine to induce quiet, to withhold food

and fluids by mouth, to supply fluids by vein and to give adequate blood transfusions

If such a practice is followed, the response to these measures falls into two main groups: some patients merely hold their own and do not improve or they continue to fail, for they are still bleeding and the blood escapes from the open artery in the base of the ulcer as rapidly as or more rapidly than it is introduced into the veins; others improve, as evidenced by physical appearance, pulse, blood pressure and other favorable signs. With the latter, it may be assumed that the hemorrhage had ceased at the time of admission or, if continuing, has greatly decreased. The fact that these patients improve is not positive proof that the hemorrhage was not derived from an open pancreaticoduodenal or major branch of the right or left gastric artery, for under a strict regimen, as indicated above, some patients suffer a second massive or even fatal hemorrhage in the next two hospital weeks; this may occur spontaneously or may be initiated by the administration of food or a swallow of barium with the purpose of localizing the lesion. Of all the criteria assembled to differentiate the cases of hemorrhage that are likely to prove fatal, the failure of hemorrhage to stop under a strict medical regimen and the recurrence of hemorrhage after it has temporarily stopped and while the patient is on a strict medical regimen are the most positive. In all cases that exhibited these manifestations the ulcer was located on the posterior wall of the duodenum, implicating the pancreaticoduodenal artery, or on the lesser curvature of the stomach, involving a large branch of the gastric artery. In passing I may say that these statements also apply to patients admitted not because of hemorrhage but because of other symptoms of ulcer who, while under a strict medical regimen, have a serious hemorrhage.

It therefore appears that among patients admitted because of serious hemorrhage there will be some — in the experience cited above, 15 per cent of the total — who die of hemorrhage that is not surgically checked. The most positive indications of such hemorrhage are the failure of improvement under a strict medical regimen, including adequate blood transfusions, with or without evidence of continuing bleeding, such as the vomiting of blood and the passage of blood by rectum, and the recurrence of hemorrhage under a strict medical regimen. Patients who present these indications must seriously be considered subjects for early operation, for otherwise a high percentage will die.

Other factors affect the seriousness of hemorrhage in ulcer. Age has been shown to be a factor by a number of authors, and the experience discussed above supports the view that hemorrhage is likelier to be serious and fatal in patients over fifty years of age. This is due not only to the higher incidence of arteriosclerosis but also to cardiorenal complications. Sex is also a factor, and it is well known that

fatal hemorrhage is less frequent in women than in men.

Thus far in my discussion I have tried to define and segregate patients with serious or massive hemorrhage in whom immediate or early operation must seriously be considered. What are the criteria in arriving at a prompt decision to operate? I have referred to patients who are admitted in profound shock and, judged by the usual criteria, present every contraindication to operation. Should operation be delayed, in the hope that the patient will improve and be less grave a surgical risk, or should contraindications be disregarded and a desperate surgical venture undertaken? Both methods of approach to the problem have been tried. Whether operation is performed early or delayed, a fairly high mortality can be expected. The question is, Which will achieve the lower mortality? From this admittedly limited experience, early operation appears to be the better choice. The principle — established in wounds of war and accidents of civil life — that active hemorrhage must be controlled before progress can be made toward saving life is equally applicable in the type of hemorrhage under discussion. In exposing an ulcer of the posterior duodenal wall with an eroded, actively bleeding, pancreaticoduodenal artery, I have not only been amazed at the amount of blood that can be poured into the duodenum in a short time but also struck with the futility of blood transfusions as a means of saving life until the bleeding vessel has been controlled.

The question of when to operate in this particular group of cases has been discussed by a number of authors, and it appears that early operation — within twenty-four to forty-eight hours after the onset of hemorrhage — will save more lives. Finsterer,³ an advocate of operation for massive hemorrhage in chronic ulcer, reports that in 59 patients operated on immediately or within forty-eight hours the mortality was 5 per cent, whereas in 53 operated on late it was over 30 per cent. Gordon-Taylor,⁶ Oliani⁷ and others also found that early operation gave better results. The experience in this hospital shows that of 21 patients operated on early, 2 died — a mortality of 10 per cent — and that of 10 operated on late, 7 died — a mortality of 70 per cent. The experience quoted indicates that operation should be promptly decided on and executed.

After operation has been decided on, one of the most important factors in a successful outcome is an unlimited amount of blood available for transfusion. The introduction of blood, previously begun in the ward, should be continued throughout the operation and after operation, according to indications. The treatment of the wounded in war demonstrated the value of large amounts of whole blood in patients with massive and continuing hemorrhage, and the situation in hemorrhage from ulcer is similar. The primary object of surgery is to con-

trol hemorrhage and save life, the treatment of the ulcer from an immediate viewpoint is secondary, as it is in acute perforation. The operative procedure of choice, then, should be the quickest and simplest that will completely control hemorrhage.

For both duodenal and gastric ulcers, the operations performed include the following: the local ligation of the artery in the base of the ulcer by an encircling ligature, the ligation of the artery or arteries outside the visceral wall, the local excision of the ulcer with the control of hemorrhage, with such additional procedures as may be necessary to re-establish the continuity of the gastrointestinal tract, and gastric resection, including the bleeding ulcer. Experience with these procedures shows that they all have some disadvantages. Local ligation of the bleeding vessel in the base of the ulcer and the ligation of vessels outside the visceral wall have not proved uniformly successful. A continuation of the ulcerative process or the cutting through of ligatures or their combination may result in a recurrence of hemorrhage during the first or second week after operation. In ulcers high on the lesser curvature of the stomach, experience with these two procedures has been particularly unfavorable. Because the lesions were so high as to encroach on the esophagus, neither local excision nor any other procedure appeared feasible. In 3 patients with lesions of this sort, hemorrhage was temporarily checked but recurred and resulted in death. Post-mortem examination showed further erosion and reopening of the blood vessels. Local excision of the ulcer with the control of hemorrhage is definitely a safer procedure from the viewpoint of permanently controlling hemorrhage. In lesions favorably situated, it can be done almost as rapidly as the preceding two procedures. In lesions of the stomach and duodenum adjacent to the pylorus, the excision of the ulcer and the necessary repair may occlude the stomach or duodenum and make necessary an additional procedure, such as a pyloroplasty or a gastroenterostomy, which prolongs operation and adds to its hazards in a depleted patient. Gastric resection with removal of the ulcer is the most formidable operation for dealing with the situation. Its duration and often its technical difficulties are disadvantages. If it succeeds, there is in addition to saving life the greater probability of curing the patient of the disease.

These are the most frequent methods of surgical treatment of the bleeding ulcer. It is apparent that rules for their use cannot be stated. The judgment of the surgeon must guide him in determining which procedure he will use in an individual case. Generally speaking, however, it can be said that local attempts at controlling hemorrhage without removal of the ulcer are the least safe of the methods of permanently controlling hemorrhage.

As I have indicated above, approximately 15 per cent of patients who enter the hospital with massive

hemorrhage die unless they can be saved by prompt surgery. Eighty-five per cent, under a careful medical regimen, including blood transfusions, recover from the hemorrhage for which they are admitted. What should the policy toward this group of patients be? As pointed out above, of 288 patients who recovered from their primary hemorrhage, 105 were subjected to operation — the large majority, to gastric resection — within four to six weeks after the primary admission for hemorrhage. There were 4 postoperative deaths, a mortality of 4 per cent. One hundred and eighty-three patients had not been operated on at the time the various studies were made but had been discharged from the hospital to be followed in the clinic.

I had hoped to be able to report the follow-up studies on the entire series of cases, but I could not complete the task in time for this meeting. I am, however, able to report on the group of 73 cases occurring between July 1, 1943, and January 1, 1946, in which 2 patients died without operation, 9 were operated on during the period of active hemorrhage, with 7 recoveries and 2 postoperative deaths, 33 were subjected to operation within four to six weeks after recovery from the hemorrhage for which they were admitted and 29 were not subjected to operation but were discharged to be followed in the clinic.

Of the 7 survivors among the 9 patients subjected to operation during the period of active hemorrhage all were subjected to gastric resection, with satisfactory results from the primary resection in 6. One had a poor result but was subjected to a second resection with a satisfactory result. The results were therefore satisfactory in this group.

Of the 33 patients subjected to operation within four to six weeks after recovery from the primary hemorrhage, 25 had primary gastric resections, 5 had secondary resections (these patients had previously been operated on), 1 had a gastroenterostomy, 1 had a ligation of the left gastric artery, and 1 had an exploratory laparotomy.

Of the 25 patients with primary resections, 1 died after operation. Of the 24 survivors, 21 at present have satisfactory results and 3 have poor results, the 3 patients with poor results have developed recurrent ulceration, with recurrent hemorrhage, but all are living at the present time.

Of the 5 patients with secondary gastric resections, 3 have satisfactory results at present. The 2 with poor results developed recurrent ulceration with hemorrhages — both were subjected to further gastric resections and both still have poor results, with recurrent hemorrhages, but are alive.

The patient subjected to gastroenterostomy has at the present time a satisfactory result. The patient subjected to ligation of the left gastric artery had a poor result, with recurrent hemorrhages. He was subjected to a gastric resection during active bleeding, with a satisfactory result at present. The patient

subjected to exploratory laparotomy without the discovery of a demonstrable active ulcer has a poor result, with recurring hemorrhages. He is living at the present time.

In summarizing this group of 33 patients it appears that they have been subjected to thirty-five operations (thirty-three gastric resections) in attempts to control hemorrhage and to prevent recurrent ulceration. There was 1 postoperative death — an operative and case mortality of 3 per cent. Of the survivors, 26 (81 per cent) have satisfactory results at present and 6 (19 per cent) have poor results with recurring hemorrhages. Gastric resection, in this group, was effective in controlling hemorrhage and preventing recurrent ulceration in 84 per cent of the cases.

Of the 29 patients discharged from the hospital without having been subjected to operation, 28 have been successfully followed. Of these, 24 have a satisfactory result from the viewpoints of both absence of recurrent hemorrhage and relief from other ulcer symptoms. Four with poor results have had recurrent hemorrhages but are living. Under a careful medical regimen, therefore, the results were satisfactory in 85 per cent of these patients.

I am unwilling to draw any definite conclusions from these data. The follow-up period is too short, for the majority of patients have been followed less than three years. From all the studies on ulcer that I have made it is evident that accurate statements regarding the effectiveness of either medical or surgical measures cannot be made on the basis of a follow-up period of less than five years, and I must add that statements based on such a follow-up period must be modified in the years that follow. Again, the data that I have presented cover only a part of the entire series, a complete study of which may show results at variance with those given. From such data as I have on the entire series, it appears that 37 per cent of these patients were subjected to early gastric resection (within four to six weeks) and that 63 per cent were treated medically. From observations admittedly incomplete I find that gastric resection, after a relatively short follow-up period, assures control of hemorrhage and prevention of recurrent ulceration in 84 per cent of cases, with a primary surgical mortality of 3 per cent. I find, also, that on the basis of a similar short follow-up period, a medical regimen may yield highly satisfactory results in selected cases. I have no positive evidence that every patient who bleeds must necessarily be subjected to surgery. But there is evidence that a certain percentage of cases should be subjected to early surgery. First, it is known that hemorrhage, with the exception of acute perforation, is the most frequent cause of death in ulcer. Secondly, it is known that although acute ulcers may give rise to serious hemorrhage, the deeply penetrating, more chronic ulcers oftener cause dangerous and fatal hemorrhage — perhaps I should

use the term "actively penetrating" rather than "chronic ulcer," for Holman et al.⁸ found that in older patients the increased mortality from hemorrhage does not bear a relation to the age of the ulcer, since the average duration of symptoms was slightly over four years in those who recovered from hemorrhage and four years in those who died. Thirdly, age, in the experience discussed above and in that of a number of authors, is a factor, more patients forty-five to fifty years of age and over being likely to suffer hemorrhages leading to death than patients in younger age groups. The higher death rate in the older age groups is not wholly due to the hemorrhage but in part to a higher incidence of complications caused by loss of blood, particularly cardiorenal complications. Again, the repetition of hemorrhage is believed by some to be of importance in determining treatment. Jordan and Kiefer,⁹ for example, found that 70 per cent of patients who had two or more hemorrhages suffered further hemorrhages. And finally, Holman¹⁰ and others have noted that patients with chronic ulcer and with a history of present or past hemorrhage do not do well under a medical regimen and are prone not only to a continuation of pain and other symptoms but also to recurrent hemorrhage. This finding is not supported by the follow-up studies in the small group of 28 cases considered above, who were not followed for a sufficiently long period of time, however.

Although these observations have a bearing on the problem of treating patients who have recovered from the hemorrhage that brought them to the hospital, it must be admitted that they are somewhat vague to be formulated into a clear-cut policy. Any policy for this group of patients cannot well be determined on the basis of hemorrhage alone, it must include consideration of the ulcer and its duration, location, pathologic characteristics and probable tendency to heal. If a patient has suffered a serious hemorrhage and harbors an ulcer that experience indicates is unlikely to respond to a medical regimen, the occurrence of hemorrhage is an added reason for surgical therapy, if experience suggests that the patient has an ulcer that is likely to respond to a medical regimen, a first or second hemorrhage should not weigh too heavily in the decision to recommend early surgery. Until more clear-cut information is available, the decision regarding therapy in this group of cases must rest on the consideration of all the factors enumerated. If surgery is decided on, gastric resection, with invariable removal of the ulcer if possible, is the operation of choice, although it does not necessarily protect the patient against either subsequent ulceration or hemorrhage.

This discussion has been confined to hemorrhage in patients with peptic ulcer. I should, perhaps, refer to a related group of patients who have massive and sometimes fatal hemorrhage but who fail to present a demonstrable ulcer. This group of patients has

been a particularly discouraging one. Pathologically, the information regarding the source or sources of hemorrhage has been meager. At autopsy the pathologist has, generally speaking, failed to find an ulcer or other causes of hemorrhage. In one case the pathologist did not find even an erosion of the mucosa of the stomach and duodenum, but when the gastric artery was connected with a pressure bottle of salt solution a jet of fluid was projected from the mucosa. The area was excised, and serial sections showed a small ruptured aneurysm covered by intact mucosa. At operation in these cases the most careful inspection and palpation of the stomach and duodenum fails to demonstrate an ulcer. In some of these cases the stomach has been opened by a long incision parallel with the greater curvature, the stomach literally turned "inside out" and the entire mucosa not only of the stomach but also of the proximal duodenum carefully examined, without the demonstration of an ulcer. In the majority of cases so examined the bleeding temporarily ceased and a source of hemorrhage was not found. Yet within a week the patient may suffer another devastating hemorrhage.

Clinically patients suffering from this type of hemorrhage often fail to present any symptoms that serve to differentiate them from those with ulcer, although a clear-cut history of ulcer may be absent. The first hemorrhage may be fatal, and the assumption is that the patient has bled from an ulcer until autopsy proves otherwise. Again, patients may have repeated hemorrhages from which they recover under appropriate treatment. A patient of one of my associates whom I saw in consultation had fifty-eight massive hemorrhages over a period of twenty-five years and had been admitted to and carefully studied in many of the important clinics throughout the country. He had been operated on in one clinic and a gastric resection performed even though an ulcer was not demonstrated. He entered the New York Hospital exsanguinated from his fifty-ninth hemorrhage. He recovered and was again operated on because of the suspicion of a duodenal ulcer. A further segment of duodenum was resected, but an ulcer was not found. After having shown such a tenacity of life for so many years, it seems a pity that the patient recently got into a fight, was knocked to the pavement and died of an intracranial hemorrhage.

So far as diagnosis and treatment are concerned, it appears to me that these cases must be classified with those of hemorrhage from ulcer. The absence of a history of ulcer is scarcely of sufficient weight for operation to be withheld in the presence of a hemorrhage immediately threatening life, and should recovery occur under expectant treatment, further studies may be helpful in determining treatment. Such a program will result occasionally in the embarrassment of the surgeon who at operation fails to find an ulcer or other source of hemorrhage.

What he is to do under these circumstances I leave to his best judgment.

SUMMARY

A study of 337 patients admitted to the hospital because of massive hemorrhage due to peptic ulcer is presented. Of these patients 27 (8 per cent) died from hemorrhage—18 without having been subjected to operation and 9 following operations performed on 31 patients during active bleeding.

In the experience on the surgical ward service of the New York Hospital-49 (15 per cent) of all patients admitted with massive hemorrhage presented a fatal type of hemorrhage and in all probability would have died without the intervention of surgery.

Two hundred and eighty-eight patients (86 per cent) admitted because of hemorrhage recovered without immediate or early surgical intervention.

In patients with the fatal type of hemorrhage the location of the ulcer, if duodenal, is on the posterior duodenal wall and, if gastric, on the lesser curvature. The blood vessels causing the hemorrhage are the pancreaticoduodenal and the right and left gastric arteries or their major branches.

In an attempt to differentiate patients with fatal and nonfatal types of hemorrhage the most consistent criteria are failure to improve promptly under a strict regimen of bed rest, moderate doses of morphine, withholding fluids and food by mouth and adequate blood transfusions and the recurrence of hemorrhage while the patient is on a strict regimen.

If operation to save life is decided on it should be done within twenty-four or forty-eight hours of the onset of hemorrhage. The mortality in patients operated on early was 10 per cent, whereas that in patients operated on late (after forty-eight hours) was 70 per cent.

Large amounts of blood administered as transfusions before, during and after operation are of great value in operations performed for the control of hemorrhage.

Local ligation of the vessels giving rise to hemorrhage has not consistently and permanently controlled hemorrhage. Local excision of the bleeding ulcer and gastric resection, including removal of the ulcer, have given the best results.

In patients who recover from hemorrhage on a strict medical regimen the question of recommending surgery or of continuing a medical regimen is vital. No definite criteria for differentiating those who should be subjected to surgery and those who may properly be continued on a medical regimen have been developed. On the other hand, age over fifty, the occurrence of repeated hemorrhages, the chronicity and unfavorable location of the ulcer and failure in the past to respond to a medical regimen are factors suggesting surgery.

ROENTGENOLOGIC EXAMINATION IN PATIENTS WITH BLEEDING FROM THE GASTROINTESTINAL TRACT

RICHARD SCHATZKI, M.D.*

BOSTON

MASSIVE hemorrhage from the gastrointestinal tract, particularly hematemesis, is one of the dramatic events in medicine that deeply impress both patient and physician. The question that presents itself urgently to both is, What is the cause of the bleeding? At times the history may give a clue to the diagnosis, whereas at others the bleeding takes place without any preceding symptoms or signs. In rare cases a blood dyscrasia, usually easily recognized, has prompted the hemorrhage, but the answer to the question usually depends on the demonstration of an anatomic lesion.

The roentgenologist is burdened with the responsibility of finding the source of bleeding in a patient who is often sick and difficult to examine. The plan of action which should be agreed on after thoughtful discussion by both the roentgenologist and the physician in charge of the patient, varies somewhat from case to case. If there is no clinical hint regarding the location of the point of bleeding—that is, whether it is in the upper or the lower part of the gastrointestinal tract—a scout film of the abdomen and examination of the large intestine should precede that of the esophagus, stomach and duodenum. A careful study of the small intestine forms the last part of the examination. Usually, however, the type of hemorrhage indicates roughly which part of the gastrointestinal tract is the source of bleeding, and the suspected region should be examined first. Massive hemorrhage in the majority of cases arises in the upper part of the digestive tract, and the question to be decided first is when the patient can best and safely be submitted to barium meal studies.

In the past the tendency was to delay such examination for two or more weeks, since it was thought that one at an earlier date not only endangered the patient but also, because of his precarious condition, furnished somewhat unreliable results. In recent years this attitude has changed, and the manifold advantages of early roentgenologic examination are recognized.

A patient may bleed from a gastric cancer, in which case delay of examination would mean delay in operation and, in turn, delay in removal of the malignant source of bleeding. Bleeding ulcers in people over fifty years of age have been shown to have a mortality higher than that in younger persons. The necessity of careful appraisal of these patients in whom early operation is preferable has been emphasized by Allen.¹ Should the necessity for surgical intervention arise, the operation is connected with greater risk unless the diagnosis has been established preoperatively. If the patient is bleeding from an ulcer, it is of advantage to the surgeon to know where the ulcer is—whether in the stomach or in the duodenum, and whether on the anterior or the posterior wall. The bleeding lesion may not be in the abdomen but higher in the gastrointestinal tract. A number of patients with esophageal varices have, in a search for the source of bleeding, been subjected to negative abdominal explorations. There is another reason in favor of early examination: a bleeding ulcer may heal within a short time, and examination at a later date may leave physician and patient with the uncomfortable mystery of unexplained hemorrhage.

In recent years the dietary regime of the bleeding patient has become more liberal, food being administered in the early days of hemorrhage. There is no reason to assume that a watery suspension of barium sulfate is more dangerous than food. In all probability it is even less so, because it does not stimulate peristalsis and secretion to the same degree that food does. For some time, following the example of Hampton,² I have not hesitated to examine a patient shortly after bleeding has stopped, or even during bleeding, although I do not examine patients in shock. The examination, without any palpation, is made with the patient in the horizontal position, peristalsis and gravity (turning him from side to side) being used as the means of distributing the barium over the inner surface of the esophagus, stomach and duodenum. So-called "spot films"—that is, films taken during fluoroscopy at the optimal moment of

been a particularly discouraging one. Pathologically, the information regarding the source or sources of hemorrhage has been meager. At autopsy the pathologist has, generally speaking, failed to find an ulcer or other causes of hemorrhage. In one case the pathologist did not find even an erosion of the mucosa of the stomach and duodenum, but when the gastric artery was connected with a pressure bottle of salt solution a jet of fluid was projected from the mucosa. The area was excised, and serial sections showed a small ruptured aneurysm covered by intact mucosa. At operation in these cases the most careful inspection and palpation of the stomach and duodenum fails to demonstrate an ulcer. In some of these cases the stomach has been opened by a long incision parallel with the greater curvature, the stomach literally turned "inside out" and the entire mucosa not only of the stomach but also of the proximal duodenum carefully examined, without the demonstration of an ulcer. In the majority of cases so examined the bleeding temporarily ceased and a source of hemorrhage was not found. Yet within a week the patient may suffer another devastating hemorrhage.

Clinically patients suffering from this type of hemorrhage often fail to present any symptoms that serve to differentiate them from those with ulcer, although a clear-cut history of ulcer may be absent. The first hemorrhage may be fatal, and the assumption is that the patient has bled from an ulcer until autopsy proves otherwise. Again, patients may have repeated hemorrhages from which they recover under appropriate treatment. A patient of one of my associates whom I saw in consultation had fifty-eight massive hemorrhages over a period of twenty-five years and had been admitted to and carefully studied in many of the important clinics throughout the country. He had been operated on in one clinic and a gastric resection performed even though an ulcer was not demonstrated. He entered the New York Hospital exsanguinated from his fifty-ninth hemorrhage. He recovered and was again operated on because of the suspicion of a duodenal ulcer. A further segment of duodenum was resected, but an ulcer was not found. After having shown such a tenacity of life for so many years, it seems a pity that the patient recently got into a fight, was knocked to the pavement and died of an intracranial hemorrhage.

So far as diagnosis and treatment are concerned, it appears to me that these cases must be classified with those of hemorrhage from ulcer. The absence of a history of ulcer is scarcely of sufficient weight for operation to be withheld in the presence of a hemorrhage immediately threatening life, and should recovery occur under expectant treatment, further studies may be helpful in determining treatment. Such a program will result occasionally in the embarrassment of the surgeon who at operation fails to find an ulcer or other source of hemorrhage.

What he is to do under these circumstances I leave to his best judgment.

SUMMARY

A study of 337 patients admitted to the hospital because of massive hemorrhage due to peptic ulcer is presented. Of these patients 27 (8 per cent) die from hemorrhage — 18 without having been subjected to operation and 9 following operations performed on 31 patients during active bleeding.

In the experience on the surgical ward service of the New York Hospital 49 (15 per cent) of all patients admitted with massive hemorrhage presented a fatal type of hemorrhage and in all probability would have died without the intervention of surgery.

Two hundred and eighty-eight patients (86 per cent) admitted because of hemorrhage recovered without immediate or early surgical intervention.

In patients with the fatal type of hemorrhage the location of the ulcer, if duodenal, is on the posterior duodenal wall and, if gastric, on the lesser curvature. The blood vessels causing the hemorrhage are the pancreaticoduodenal and the right and left gastric arteries or their major branches.

In an attempt to differentiate patients with fatal and nonfatal types of hemorrhage the most consistent criteria are failure to improve promptly under a strict regimen of bed rest, moderate doses of morphine, withholding fluids and food by mouth and adequate blood transfusions and the recurrence of hemorrhage while the patient is on a strict regimen.

If operation to save life is decided on it should be done within twenty-four or forty-eight hours of the onset of hemorrhage. The mortality in patients operated on early was 10 per cent, whereas that in patients operated on late (after forty-eight hours) was 70 per cent.

Large amounts of blood administered as transfusions before, during and after operation are of great value in operations performed for the control of hemorrhage.

Local ligation of the vessels giving rise to hemorrhage has not consistently and permanently controlled hemorrhage. Local excision of the bleeding ulcer and gastric resection, including removal of the ulcer, have given the best results.

In patients who recover from hemorrhage on a strict medical regimen the question of recommending surgery or of continuing a medical regimen is vital. No definite criteria for differentiating those who should be subjected to surgery and those who may properly be continued on a medical regimen have been developed. On the other hand, age over fifty, the occurrence of repeated hemorrhages, the chronicity and unfavorable location of the ulcer and failure in the past to respond to a medical regimen are factors suggesting surgery.

525 East 68th Street

to discuss them all, but a few are selected to show some of the problems with which the roentgenologist is confronted

By far the most frequent cause of bleeding is a duodenal ulcer, and good demonstration of the duodenal cap is one of the important factors in the examination. Hampton's maneuver, described above, is indispensable for this purpose, since most bleeding ulcers arise from the posterior wall and are particularly well demonstrated in this position. A normal-appearing cap does not rule out bleeding from a duodenal ulcer, since the ulcer may lie distal to the cap. Another diagnostic error may be caused by a large ulcer that replaces the entire area normally occupied by the duodenal cap and thus simulates a normal cap.

Gastric ulcers, particularly if they are not large, may disappear with unexpected speed. I have seen bleeding ulcers disappear within two weeks. As mentioned above, routine roentgenograms taken in the horizontal position may miss ulcers, particularly those high on the lesser curvature and posterior wall. Spot films, taken with the patient face up and turned on the right side, show the crater through the air of the stomach. If the ulcer lies on the posterior wall, it may be clearly seen in profile in this position.

If the bleeding is from cancer, and the cancer is large, fluoroscopy and a single spot film may be sufficient to demonstrate it. Blood clots, however, may produce a picture similar to polypoid tumor and in questionable cases should be excluded by re-examination. It should be borne in mind that a blood clot may remain unchanged in the stomach for some time, particularly if the patient has anacidity.

One of the great advantages of early examination is the possibility of diagnosing, and to a certain extent excluding, varices of the esophagus. If varices are demonstrated, in all probability the source of bleeding has been found. Varices may be present in the absence of splenomegaly, ascites and palpable liver anomalies, and hemorrhage may be the only clinical symptom. On the other hand, not every patient with demonstrable varices bleeds. The recognition of varices is difficult at times. The esophagus, if filled with enough barium, may appear practically normal except for a slight widening, or peristalsis may empty the dilated vessels, producing a normal appearance. Even when extensive varices are present, only the relief picture may reveal the vascular phenomena. The relief picture represents the barium coating of the esophagus after the main bolus has passed through it. Varices occasionally extend into the stomach, and their appearance suggests a tumor in the fundus, in rare cases they are confined to the stomach. Under these circumstances, their diagnosis is extremely difficult.

Gastritis, particularly if many erosions are present, may cause marked hemorrhage. The roent-

genologic diagnosis of gastritis is difficult and is possible in only a small number of cases. The erosive form, in which bleeding is most frequent, is rarely demonstrable, but if it is, the characteristic appearance is one of multiple shallow craters surrounded by a halo of edema. In acute alcoholic gastritis, which often causes hemorrhage, one sees evidence of marked hypersecretion with some swelling of the folds. At times this swelling produces a tumorlike appearance, but it usually disappears within a few days. On the other hand, in gastritis, the stomach may appear completely normal roentgenologically, and only by gastroscopy may the diagnosis be made.

Hemorrhage from a hiatus hernia is easily understood if a large crater is seen in the ring of the hernia, but bleeding occasionally occurs without ulcer. I have seen cases in which at autopsy nothing was found to explain the patient's hemorrhage except erosive gastritis, particularly in the herniated portion of the stomach.

Repeated hemorrhage without other clinical symptoms is often found in tumors that arise beneath the mucosa of the stomach wall — the so-called "spindle-cell tumors," which include leiomyomas, fibromas, neurofibromas and their malignant variants. Their roentgenologic appearance is similar and characteristic.

Examination of a bleeding patient should not be stopped at the duodenal cap. Tumors of the duodenum are rarer than those of the stomach, but every roentgenologist of experience has seen a fair number of them. They are frequently missed unless they are carefully looked for. Demonstration of a possible source of bleeding should not prevent one from continuing the examination to its completion unless the patient is in a precarious condition, since at times another bleeding lesion is found. I have seen, for instance, a bleeding fibrosarcoma of the third portion of the duodenum in a patient with a large duodenal crater that at first had seemed to explain the hemorrhage.

Only a few examples have been selected to demonstrate the problem with which the roentgenologist is confronted in dealing with a bleeding patient. A large number of other lesions, especially those in the small intestine and colon, have been omitted from this discussion.

SUMMARY

The roentgenologist plays an important role in the handling of a patient bleeding from the gastrointestinal tract. In most cases he is burdened with the responsibility of demonstrating the anatomic lesion that has caused the hemorrhage, and to do so it may be necessary to examine every portion of the gastrointestinal tract.

The routine roentgenologic examination of the upper gastrointestinal tract in a bleeding patient is described.

filling and projection — are taken whenever they are deemed advisable and are of great help

* * *

It may be worth while to describe the routine procedure in the roentgenologic examination of the upper gastrointestinal tract in a patient who has had a recent hemorrhage. He is placed in the supine position, rotated slightly to the left. A swallow of barium is followed through the esophagus fluoroscopically, and the presence of large varices may be detected. Further examination of the esophagus is postponed until the end of the examination, to prevent overfilling of the stomach at this stage. An additional two or three swallows are usually needed to outline the posterior part of the fundus of the stomach. Complete filling of the fundus is not obtained at this point, since it necessitates too much barium. The patient is then rotated to the right side until a point has been reached where the barium leaves the fundus and falls slowly through the body toward the antrum. More barium is given, and the stomach is observed until most of that from the fundus has emptied into the lower portion of the stomach. In this position the lesser curvature forms the dependent portion of the stomach, and ulcers may be seen clearly, face on, through the air that fills the greater portion of the body of the stomach. The significance of this position cannot be overemphasized.

The patient is then returned to the supine position and rotated slowly to the left side. This maneuver tends to produce reasonably complete filling of the upper half of the stomach. If the turning of the patient is continued until he is on his face, incomplete air demonstration of the fundus and massive filling of the lower half of the stomach result. The examination of the esophagus in both oblique diameters is completed while the patient is lying on his stomach. The examination of the duodenal cap has been described in detail by Hampton.² The outline of the cap is usually seen while the patient is in the face-down position. Better demonstration of the shape and of the relief of the cap is obtained, however, in the last phase of the examination: the patient is turned on his right side, the cap being allowed to fill with barium, after which he is returned to the supine position and to his left side. This permits the air in the stomach to reach the cap and produce an air-and-barium contrast picture of the cap (Hampton's maneuver). In the same position the antrum and second portion of the duodenum may be demonstrated with contrast filling.

Complete rotation of the patient is not always necessary, since the source of bleeding may be discovered after the first few swallows of barium or a single spot film may be sufficient for its demonstra-

tion, when the patient may return to the ward. In the patient with active hemorrhage for whom the prone position is thought to be inadvisable for clinical reasons, this part of the examination may be omitted and the patient studied only on his back and on his side, this omission will reduce somewhat the completeness of the examination.

The early examination, as described above, is adequate for study of the esophagus and satisfactory for examination of the duodenum, but it does not always demonstrate the entire stomach. The only real danger involved is in the transport of a patient bleeding from the gastrointestinal tract. I consider this danger negligible if a sudden increase in intra-abdominal pressure is prevented, and this can be avoided by lifting the patient on the bed sheet from the stretcher to the examining table and back again.

Good clinical judgment and common sense are essential in the selection of bleeding patients for early examination. Obviously a patient should not be examined during clinical shock. It is usually unnecessary to examine one while he is actively bleeding. Blood clots that lie in the stomach handicap the proper interpretation of the roentgenograms, although they do not prevent diagnosis of varices of the esophagus, large ulcers of the stomach or ulcers of the duodenum. It appears reasonable to wait at least twenty-four or forty-eight hours after an acute, massive hemorrhage. Early examination may be necessary if the patient has had previous gastrointestinal bleeding whose cause was not found, or if he shows evidence of continued arterial bleeding calling for immediate surgery. Such cases are the exception, however, and in general it is wise to postpone examination until the active, massive bleeding has subsided. If the source of hemorrhage is known from a previous examination, re-examination may be delayed until the patient's condition permits study in the upright as well as in the horizontal position. It would be useless, for example, to submit the patient and the roentgenologist to the difficulties of early examination in a case of known duodenal ulcer admitted to the hospital because of a fifth bleeding episode.

Any patient in whom early examination has not demonstrated the cause of hemorrhage should be re-examined at a later date when palpation is possible and he is permitted to stand. Some bleeding lesions are better demonstrated during the early examination, and others at the later, more convenient and more thorough one. In spite of every diagnostic maneuver known to the roentgenologist, the source of bleeding in a certain number of cases will remain obscure.

* * *

The lesions that produce hemorrhage from the gastrointestinal tract are manifold. It is impossible

throats This organism was also isolated from the throats of 3 of 21 other patients, in whom cultures were taken, for the most part toward the end of the outbreak. The first 3, with a moderate leukocytosis, as demonstrated by an average white-cell count of 12,100, were given chemotherapy. Of the 11 cases of otitis media, only 1 became purulent and required chemotherapy. White-cell counts

or the Lee strain of influenza B, the procedure has been described elsewhere in detail.¹ In Group 1 the average final titer, determined as the reciprocal of the final dilution of serum before the addition of sensitized cells, was definitely elevated against influenza A — 1:421, or over twice as high as the titer of 1:192 (1:64 in the initial dilution of serum) regarded by Eaton and Rickard² as presumptive

FIGURE 1 Incidence of Cases

The empty squares represent case admitted because of upper respiratory infection, the cross-hatched squares, those tested for complement-fixing antibodies during the convalescent stage, and the black squares, those tested for complement-fixing antibodies during the acute and convalescent stages

taken in 6 of these cases ranged between 7800 and 23,200, averaging 16,500. The 3 cases of pneumonia were clinically similar to so-called "primary atypical pneumonia of unknown etiology," but the patients had relatively high initial white-cell counts (average 18,500) that remained elevated for several days and then responded to penicillin.

Serologic studies were made in 8 cases during the convalescent stage, twelve to seventeen days after the onset of symptoms (Group 1), and in 7 others during both the acute, that is, the first three days, and convalescent stages (Group 2). Patients in the former group are indicated in Figure 1 by cross-hatched squares, and those in the latter by black squares.

Complement-fixation tests were carried out with the use of the allantoic fluids from embryonated eggs infected with the PR8 strain of influenza A

evidence of recent infection. Furthermore, 7 of the 8 patients tested showed titers of 1:192 or higher. The average titer against influenza B was 1:57, and in 1 case the titer was elevated, being 1:384.

In Group 2 the average titer against influenza A was approximately ten times as high in serums taken in the convalescent phase of the infection as in those taken in the acute phase, — 1:495 in the former and 1:42 in the latter, — and in 5 cases the titer increased fourfold or more following recovery. The average titer against influenza B was 1:90 in the convalescent and 1:09 in the acute phase. In only 1 case was there an increase in antibody reaction to influenza B, and in this case the titer during convalescence was relatively low, making the interpretation of the test uncertain.

Indications and contraindications for roentgenologic examination soon after, or during, hemorrhage are discussed

In spite of the most careful examination, the cause of bleeding may remain roentgenologically obscure

AN OUTBREAK OF INFLUENZA A IN A BOYS' SCHOOL*

THEODORE H INGALLS, M D,† J ROSWELL GALLAGHER, M D,‡ AND JOHN F ENDERS, M D§

BOSTON AND ANDOVER, MASSACHUSETTS

FOLLOWING the Christmas vacation of 1945-1946, there were admitted to the infirmary of a boys' school of about 680 boarding students, located thirty miles north of Boston, several boys with "colds" characterized by enough malaise so that the patients willingly sought medical advice. After hospitalization of the first patient 30 patients were admitted for upper respiratory infections during the next ten days, 138 more during the second ten-day period and 46 more during the third ten days. The outbreak then subsided. The epidemiologic data are presented graphically in Figure 1.

CLINICAL ASPECTS

These illnesses of the respiratory tract were diagnosed clinically as common cold in 87 cases, influenza in 97, acute pharyngitis in 14, otitis media in 11, hemolytic streptococcus pharyngitis in 3 and primary atypical pneumonia of unknown etiology in 3.

Detailed questioning of 50 patients selected at random disclosed that the onset of symptoms was gradual in 46 and abrupt in 54 per cent. Constitutional symptoms included malaise in all cases, headache in 68 per cent, chilliness in 44 per cent and muscle aches in 26 per cent. Cough was noted in all cases, coryza and a sore or "scratchy" throat in 68 per cent and earache in 32 per cent.

In about 80 per cent of the cases the first symptom was one referable to the upper respiratory tract, such as a sore or "scratchy" throat, "stiffness," "sniffles" or a "cold" or cough. In the remaining 20 per cent the first symptom was malaise or prostration.

The symptom of malaise is more difficult to define than it is to experience. The statement that malaise was present in all cases means that all the 50 patients questioned minutely felt "lousy" at approximately the time they sought hospitalization. This word usually chosen by the patient, although

of doubtful elegance, has the merit of being unmistakable in its connotation of lack of well being. A more accurate picture of the systemic symptoms is afforded by the fact that whereas all the boys interrogated had at least transient malaise, only 21 per cent of the whole group had abnormal fatigue and weakness — that is, prostration — as evidenced by remarks made on the infirmary records.

Likewise the fact that all those closely questioned had cough needs some qualification. In many cases the reply to the question, "Did you have a cough at any time?" was, "Well, not enough to speak about." Further interrogation, however, elicited the information that such a patient had a slight "hack" or a "scratchy cough." Cough was thus present to a greater or less degree in each member of this group but was noticeable enough to be recorded in the infirmary records in only 20 per cent of the total number of patients.

PHYSICAL AND LABORATORY FINDINGS

As one might suspect, objective signs were scant except for injection of the mucous membranes of the nasopharynx or the tympanum and for a variable amount of coryzal discharge.

The average temperature was 101°F at the height of the illnesses, — usually at or shortly after admission, — the range being between 98 and 104°F. There was nothing distinctive about the charts, which showed, in general, a fairly rapid return to normal recordings during the first day or two of hospitalization.

White-cell counts revealed a definite although slight leukopenia on the average. In 25 cases with all the clinical signs of influenza, the white-cell count ranged between 2600 and 9600, with an average of 5500. In the serologically studied group, counts in 6 cases ranged between 4100 and 8600, averaging 5800, on admission. In 1 case a white-cell count of 7600 on admission was found to be 4800 during the height of the illness, with a return to 8300 before discharge.

During the outbreak, there were remarkably few clinical complications. Three patients were diagnosed as having a hemolytic streptococcus pharyngitis, the organism having been cultured from their

RADIATION TREATMENT OF LOCALIZED MALIGNANT LYMPHOMA*

GEORGE W. HOLMES, M.D.,† AND MILFORD D. SCHULZ, M.D.‡

BOSTON

THE term "malignant lymphoma" has been rather generally accepted, in America at least, to designate malignant tumors that are characterized by progressive enlargement of lymphoid tissue in various parts of the body. Pathologists have subdivided this group on a histologic basis into several more or less characteristic types. Clinically, the disease as a rule progresses with a varying degree of rapidity to a fatal termination, the average duration of life being from two to three years.¹ Gall and Mallory² reported 10 cases with survival, free of disease, for six years or more after surgical removal. In a more recent paper, Gall³ added to the number. Jackson and Parker⁴ report survivals up to twenty-four years, and others¹ claim fairly long survival rates.

That a certain number of patients with malignant lymphoma have been cured of their disease there can be no doubt. What are the factors responsible for these unexpected, favorable results, and can the same results be obtained with properly applied irradiation as with surgical procedures? It is with these questions that the present paper is concerned.

As in other types of malignant tumors, cure in malignant lymphoma may be assumed to depend on the extent of the disease at the time treatment was undertaken, as well as on the histology, the location of the tumor and the effectiveness of the treatment. Experience has shown that widely disseminated malignant tumors are not curable by any method of treatment at present available. Cure seems to depend on complete removal or destruction of the primary tumor before it has had an opportunity to spread beyond its immediate site.

Is there a time in the life history of a malignant lymphoma when it, like other forms of malignant tumors, may be considered a localized disease? Recent opinion seems to favor an affirmative answer to this question. Gall reports a patient who died of intercurrent disease four and a half years after the successful surgical removal of a follicular lymphoma of the inguinal lymph nodes. Autopsy failed to show any evidence of lymphoma. Further confirmation of this assumption is obtainable from a review of all patients who have survived, free of disease, for long periods. In nearly all such cases a localized lesion was present when treatment was undertaken.

On the supposition that the preceding hypothesis is correct, we have reviewed the records of approximately 500 patients with malignant lymphoma treated at the Massachusetts General and the

Collis P. Huntington Memorial hospitals, and selected for particular study only those who were alive and apparently free of disease five years or longer in whom the lesion at the time of treatment was localized and who were treated with irradiation only, biopsy excepted. We have attempted to determine whether the favorable results in this group were due to the type of the lesion, the location of the lesion or the method of treatment, or whether no explanation could be obtained.

Histologic Classification

If the leukemias and the paraganuloma of Jackson and Parker⁴ are excluded, two classifications are generally accepted in this community — that of Gall and Mallory² and that of Jackson and Parker.⁴ The classifications are as follows:

GALL AND MALLORY	JACKSON AND PARKER
Stem-cell lymphoma	Reticulum-cell sarcoma
Clasmatoctytic lymphoma	
Lymphoblastic lymphoma	Lymphosarcoma
Lymphocytic lymphoma	
Hodgkin's lymphoma	Hodgkin's granuloma
Hodgkin's sarcoma	Hodgkin's sarcoma
Follicular lymphoma	Giant follicular lymphoma

It will be noted that, except for slight differences in nomenclature, there is no marked divergence in classification.

Material

We have been able to collect 15 cases in which the histories conform with the problem as outlined — a single lesion at the time of treatment (which consisted primarily of radiation), diagnosis established by biopsy and the patient living and free of disease more than five years after the last course of treatment. Table 1 gives the pertinent data on this group of patients. Five were males, and 10 were females. The youngest was ten, and the oldest fifty-eight years old, the average age being thirty-seven years. The location of the lesion varied. There were abdominal tumors, either in the mesenteric lymph nodes or in some part of the gastrointestinal tract, in 4 cases. The tumor was in the peripheral lymph nodes in 5 cases, the involved nodes being in the neck in 4 and in the groin in 1. The remaining tumors were in the tonsil in 2 cases, the larynx in 1, the parotid gland in 1, the femur in 1 and the skin in 1.

Histologically, there were 2 stem-cell, 1 clasmatoctytic, 6 lymphoblastic, 3 lymphocytic and 1 Hodgkin's lymphoma, 1 Hodgkin's sarcoma and 1 follicular lymphoma.[§]

§Slides of all these tumors were reviewed microscopically in 1946 in the Department of Pathology, Massachusetts General Hospital.

DISCUSSION

The results of the complement-fixation tests in Group 1 alone afford presumptive evidence for regarding the outbreak as predominantly due to influenza A. With one exception, no titer as high as 1:192 was obtained for influenza B. Although infections caused by influenza B had been prevalent in the eastern United States about two months previously, with this one exception, only extremely low concentrations of antibody, or none at all, were demonstrated. More conclusive serologic evidence that the outbreak was due to influenza A is afforded by the results of the tests on the 7 patients in Group 2.

Since an etiologic diagnosis of influenzal infection is at best equivocal on clinical criteria alone, it is of interest to compare clinical diagnoses in the serologically proved cases with those made during the course of the whole outbreak (Table 1). Although

TABLE 1 Diagnoses in All and in Serologically Positive Cases

DIAGNOSIS	ALL CASES		SEROLOGICALLY POSITIVE CASES	
	NO OF CASES	PER-CENTAGE	NO OF CASES	PER-CENTAGE
Otitis media	11	5	1	7
Common cold	87	40	5	33
Influenza	97	45	9	60

the number of serologically tested patients was small, it represented a rough cross section of the outbreak. Accordingly, the variations in clinical diagnosis appeared to reflect for the most part variations in the symptomatology rather than in the etiology of the disease.

It will be observed that during the outbreak, almost as many common colds were diagnosed as were cases of influenza. Of the 50 boys carefully questioned, 28 per cent regarded themselves as merely suffering from a cold and as doing the sensible thing by reporting to the infirmary. That this commendable attitude was not altogether a lofty application of principles of preventive medicine is suggested by the fact that four times as many boys reported on Sundays—usually in the late afternoon—and Mondays as on Saturdays. (The numbers reporting on different days of the week, beginning Saturday, were 11, 46, 45, 32, 22, 26 and 33.) The questionnaire was directed only to the hospitalized group, however, and it is evident that any infected boy who did not feel sick enough to report to the infirmary, if he had any symptoms at all, regarded himself as merely suffering from a cold. One of the three authors had a cold during the

outbreak, but was able to continue working, another had influenza, requiring him to go to bed for a few days.

Although this work is in no sense meant to be construed as a study of "colds," it is pertinent to stress the fact that almost half the patients, as diagnosed by both medical and lay criteria, had common colds. These findings serve to emphasize earlier observations that clinical symptoms of different types of respiratory infections may overlap so much that the clinical differentiation is generally unreliable.* It is apparent that a cold may be both a symptom and a sign, and that even the diagnosis "common cold" is symptomatic rather than etiologic.

Finally, it is of interest, in view of our findings, to refer to the epidemiologic prediction of the Fort Bragg Commission on Acute Respiratory Diseases⁴ based on observations of the cyclic character of influenza outbreaks. The commission stated that the probabilities were seven out of eleven that influenza A would reappear during the winter of 1945-1946. This reappearance of influenza A in what up to midwinter had been an influenza B year is all the more interesting in that the "present theory" of the commission also called "for a widespread epidemic [of influenza B] before the summer of 1946."

SUMMARY

An epidemiologic and clinical description of upper respiratory infections occurring in a boys' boarding school in January and February, 1946, is given.

Complement-fixation tests were made for influenza A and B on the serums of 8 boys during convalescence and of 7 others during both the acute and convalescence phases. The average titer against influenza A among the convalescent patients was found to be more than double that considered presumptive evidence of recent infection. When the seven paired serums were tested, the average titer during the convalescent phase was found to be approximately ten times as high as that during the acute phase.

On the basis of the serologic evidence in this outbreak, the virus of influenza A appeared to be the predominant etiologic agent.

if the destruction of the tumor is complete. The radiation dosage should be large enough to accomplish this. In some cases the dosage may be as little as 600 r, but as a rule it is wiser to give as much as the normal tissues will tolerate without undue damage. With supervoltage (1200 kilovolts) and heavy filtration, the dosage may be as high as 2000 r.

Calcium and Phosphorus

Calcium and phosphorus are predominantly localized in bone, but both elements occur in the cell,⁸ phosphorus being particularly important. Inorganic phosphate is the chief anion in the intracellular fluid, and the organic phosphates of the cell appear to have considerable significance in the metabolism of fats and carbohydrates, the energetics of cellular activity and the physiology of muscular contraction. The extracellular water content of calcium and phosphorus is small in absolute amounts, but it is vital in the maintenance of normal neuromuscular irritability and bone structure. In addition, both substances play a role in acid-base regulation of body fluids. As with the other electrolytes, both ions are constantly undergoing exchange and exist in dynamic equilibria.^{74, 75}

Calcium exists in the plasma in two forms — one completely ionized and highly diffusible, and the other bound to protein and indiffusible. A small proportion is also indiffusible because it is linked to phosphate and citrate in colloidal aggregates.⁸ The inorganic phosphate of the plasma diffuses readily through colloid membranes and is apparently not bound to protein.^{4, 76} About half the phosphorus in the plasma is incorporated in the molecules of various lipids and fatty acids that may participate in base binding.⁷⁷

The plasma concentrations of ionic calcium and phosphate are resultants of the interaction of many factors. Chief among these are the relative concentrations of protein, hydrogen and bicarbonate ions. Moreover, calcium and phosphate levels tend to vary reciprocally under most circumstances for reasons that are not understood. It is now well established that the secretion of the parathyroid

glands, parathormone, is influential in controlling the concentrations of both ions.⁷⁸ The manner in which parathormone accomplishes this is a matter of controversy. On the one hand, it is believed that parathormone reduces the phosphate concentration by decreasing its renal tubular reabsorption,^{79, 80} the subsequent hypophosphatemia inducing hypercalcemia and mobilization of fixed calcium physicochemically, and on the other, that parathormone acts directly on the bone to mobilize calcium.^{81, 82} There is evidence that both actions may occur.⁸³ Finally, normal calcium-phosphorus metabolism depends on adequate dietary intake and intestinal absorption. Vitamin D is essential to the latter.

Both calcium and phosphorus are important constituents of the glomerular filtrate. During the passage through the tubules, both are reabsorbed by separate mechanisms and conserved or discarded in accordance with the needs of the body and the demands of the various processes in which they participate.

Relatively little is known about the mechanism of tubular calcium reabsorption. The calcium in the glomerular filtrate, which is limited to the ionized fraction, apparently undergoes extensive reabsorption.⁴ Hypercalciuria results when calcium is injected intravenously⁸⁴ and during hypercalcemia in hyperparathyroidism.⁸⁵ These findings suggest that the reabsorptive mechanism can be saturated, but this possibility has never been examined quantitatively.

Convincing quantitative evidence that phosphate is removed from tubular urine by a mechanism of limited capacity is now available.⁷⁶ At high plasma levels of phosphate, the rate of reabsorption becomes constant and excess phosphate is lost in the urine. This maximal activity is inhibited by glucose reabsorption. Nevertheless, an independent mechanism is apparently involved since phlorrhization enhances phosphate reabsorption whereas it halts

The x-ray dosage given was 1000 r or less in 9 cases, between 1000 r and 2000 r in 4 and over 2000 r in 2, extensive radium treatment was given in 1 case

Analysis of Factors

Location The location of the tumor does not seem to be the predominant factor on which survival can be based, but it is of some importance. In 4, or about a third, of the patients the lesion was in the abdomen. This percentage is quite comparable to that

confirm this supposition, but the number of cases is too small to warrant a positive statement.

Extent of lesion No long survivals, apparently free of disease, occurred in patients with multiple lesions. Localization of the disease at the time treatment is undertaken is probably an essential factor for lasting cure.

Method of treatment The work of Gall and Malory appears to show that complete surgical removal may produce permanent cure, and our findings in-

TABLE 1 Data in Patients Apparently Free of Disease More Than Five Years after Treatment

AGE yr	SEX	PATHOLOGICAL DIAGNOSIS	LOCATION OF TUMOR	ONSET OF DISEASE	TREATMENT AND DOSAGE	FIRST TREATMENT	LAST TREATMENT	LAST EXAMINATION	SURVIVAL	
									SINCE ONSET yr	SINCE TREATMENT yr
55	F	Stem cell lymphoma	Ileum	Oct., 1939	Radium (++++)	Nov, 1939	Feb. 1940	Dec., 1945	6 2/12	5 10/12

found by Gall. In another 5 cases, the lesion was in the peripheral lymph nodes, and in the remainder, in various other locations. Among students of this disease, there is a general opinion that when malignant lymphoma is localized, particularly in the gastrointestinal tract — or in the long bones⁵ — and can be completely removed, a cure may be expected in a fair percentage of cases. Our findings may be interpreted as confirming this belief. Otherwise, the location of the single lymphomatous tumor seems to be unimportant.

Histology It is known that the duration of life in a given case is somewhat dependent on the type of tumor present, and one would expect the chance of permanent cure to be best in the slowly growing, less malignant tumors. The data presented do not

indicate that the same results may be obtained by irradiation, provided the dose is sufficient to destroy the tumor. The minimum dose that will produce this result is not known, and our data do not give additional information. The smallest dose given was 600 r, and the largest 3000 r. Some of the tumors must have been extremely radiosensitive and others quite resistant, unless it is to be assumed that in some cases recovery was spontaneous.

CONCLUSIONS

Localization of the disease in malignant lymphoma, as in other malignant tumors, is a most important factor in suggesting a favorable prognosis. Apparent clinical cure or remission may be obtained by irradiation as well as by surgical removal.

ported cases among Northern Chinese that appear to resemble those usually described as renal rickets in which the plasma phosphate concentration remained low. All these conditions, and possibly some others, must be considered apart from the more frequent syndrome of hypocalcemia, hyperphosphatemia and acidosis that leads to bony distortions during protracted renal insufficiency.

In the controversy regarding renal rickets, it is evident that several areas of disagreement may be defined. In the first place, it appears that the name "renal rickets" may be misapplied, since most pathological studies have revealed that the bone lesion is identical with that produced by hyperparathyroidism — generalized osteitis fibrosa^{95, 105}. It is agreed that the failure of epiphyseal closure seen on x-ray examination denotes a rachitic alteration, but on the whole the roentgenographic findings are not helpful in reaching a decision. Earlier workers¹⁰⁵ considered the bone lesion similar to that of rickets, but their descriptions tally, for the most part, with the pathological picture of osteitis fibrosa. Recently, Folis and Jackson¹⁰⁷ found microscopic changes in the bone in 19 of 39 cases of chronic renal insufficiency in adults, in most of which it appeared that broadening of the osteoid sheaths of the bone trabeculae and increased bone destruction, with replacement by fibrous tissue, occurred simultaneously. They interpreted these changes as evidence of coexistent osteomalacia and osteitis fibrosa, and claimed that osteomalacic alterations were predominant. These conclusions are in disagreement with those of Ginzler and Jaffe¹⁰⁵ in a similar series and await confirmation. In general, the mass of evidence favors the view that osteitis fibrosa is the typical lesion.

The discovery of parathyroid hyperplasia, together with the demonstration of osteitis fibrosa, in many of these cases, has elicited enthusiastic claims that the condition should rightfully be called "renal hyperparathyroidism" and that excess production of parathormone is responsible for the bone lesions^{105, 109}. The weight of the evidence now available in the literature appears definitely to favor the view that parathyroid hormone may cause decalcification of bone in experimental animals after bilateral nephrectomy,⁹⁵ but it is also clear that the development of acidosis contributes heavily to the process of bone resorption. Hence, it is possible that parathormone is active in chronic renal insufficiency, but it cannot be accounted the chief cause of bone change. Since it has been pointed out that the histology of secondary parathyroid hyperplasia differs strikingly from that of primary disease,⁹⁶ it is possible that parathormone production in man is in no way comparable to the dosage administered nephrectomized rats, as described by Ingalls et al.⁹⁵ The causes for secondary hyperplasia remain obscure, attention having been

paid to hypocalcemia,⁹⁵ hyperphosphatemia,¹¹⁰ total calcium-phosphorus imbalance¹⁰⁵ and acidosis.⁹⁵ It has been suggested that the hypertrophy represents compensation rather than overactivity, in response to the need for maintaining the ionic calcium content of plasma.⁹⁵

Since acidosis is always present and since acidosis and a low-calcium diet have been found to produce osteitis fibrosa in experimental animals,¹¹¹ it seems not unlikely that chronic acidosis may be at the root of the disorder. This factor would be expected to result in mobilization of calcium from the bones and, in the presence of renal insufficiency, in a reduction of the absorption of calcium from the bowel. Ginzler and Jaffe¹⁰⁵ suggest that periods of fluctuation of renal insufficiency and acidosis with new-bone deposition, followed by further resorption, may be expected to produce the degree of osteosclerosis they observed in their series. In line with the view that insufficient calcium absorption occurs are the findings that vitamin D administration occasionally results in improvement⁹⁵ and that the fecal loss of calcium is too small to arise from excessive withdrawal from bone.⁹⁵ It seems more probable that a persistent reduction of calcium absorption is operative.

A somewhat different type of osseous abnormality, compatible with normal growth, has been described in nephrotic children. Emerson and Beckman¹¹² have consistently found hypocalcemia, mainly attributable to a deficiency of the protein-bound fraction, in these patients associated with rarefaction of the diaphyses of bone. No abnormality of epiphyseal calcification was noted, however. For some reason, calcium uptake from the bowel was markedly reduced and renal excretion of calcium fell, apparently as a result of the need for calcium conservation. This metabolic abnormality has been described in other cases.¹¹³ The changes often cleared during remissions of the disease, when the plasma protein concentration returned toward normal.

Other Electrolytes

So far as their relative plasma concentrations are concerned, the remaining electrolytes of the body fluids are unimportant. Moreover, so far as knowledge goes, it appears that these substances acquire little added significance during renal insufficiency, although it must be admitted that the information at hand is unsatisfactory, since these substances are difficult to determine.

Sulfate retention is known to occur^{114, 115} and probably contributes to acidosis. This ion is excreted efficiently by the kidney, undergoing little reabsorption during its passage through the tubules.¹¹⁶ It is interesting that sodium chloride excretion is depressed when sulfate ions are present in excess, and it is possible that this is a contributing factor in certain cases of salt retention. Sulfate

that of glucose. Parathormone is also considered to reduce phosphate reabsorption.⁸⁶ The phosphate salts in the urine play a significant role in the excretion of hydrogen ion, as pointed out above, but it now appears that acid-base imbalance has no influence on their tubular reabsorption.⁷⁶ It seems possible to explain claims to the contrary⁸⁷ on the basis of changes in the quantity of phosphate available for excretion rather than on the basis of renal functional alteration.

In renal insufficiency the reduction of filtration depresses the renal excretion of both phosphate and calcium. It is a curious, and thus far inexplicable, fact that only phosphate is retained, as a rule, in this situation. The retention of phosphate leads to depression of the calcium ion level and increased loss of calcium in the feces. The preferential retention of phosphorus may be accounted for on the basis of dietary imbalance, since the diet usually contains somewhat more phosphorus than calcium.⁸ The renal excretion of calcium and phosphorus generally parallels the intake, but with loss of renal control it is possible that phosphorus accumulates more rapidly than calcium and thus sets in motion other reactions that produce hypocalcemia. This point of view is supported by the fact that low-phosphorus diets⁸⁸ or increased fecal excretion of phosphorus following the ingestion of precipitating agents, such as aluminum hydroxide,⁸⁹ may correct the calcium-phosphorus imbalance during uremia. The recent demonstration of phosphate mobilization during stress^{90, 91} provides another possible explanation of hyperphosphatemia in uremia.

Hypocalcemia can develop, however, in the absence of phosphate retention, apparently as a result of impaired intestinal absorption.^{85, 92} Since vitamin D does not wholly correct this defect, it has been suggested that inactivation of the vitamin may occur.

Tetany due to a diminished plasma concentration of calcium ions is a frequent feature of uremia. As a rule, its manifestations are mild, consisting of muscle cramps and twitching and hyperirritability of motor nerves. Occasionally, however, convulsive seizures occur. Mason and his co-workers⁹³ have found that tetany and convulsions follow the reduction of calcium ion concentration in the cerebrospinal fluid rather than in the plasma.

Bony abnormalities may develop in renal insufficiency of long duration associated with chronic acidosis. Growing children in particular may present striking changes resembling rickets, often with serious deformities due to maldevelopment, epiphyseal separation and pathologic fractures. Adults seldom suffer from a severe grade of skeletal involvement, but histologic alterations may be found in most cases. In addition, so-called "metastatic calcification" may occur. Mönckeberg's medial sclerosis or diffuse calcification may involve the

arteries, and calcium plaques may appear in the subcutaneous tissues.^{94, 95}

Medical writings on these subjects are conflicting and confused, little agreement has been reached regarding either the cause or the character of skeletal changes. This controversy is evident in numerous descriptive terms that include "renal rickets," "renal osteomalacia," "renal dwarfism," "renal hyperparathyroidism," "renal osteodystrophy" and "renal osteitis fibrosa."

It is generally agreed that protracted renal insufficiency, chronic acidosis, low plasma calcium concentration and phosphate retention are common to most of these cases. Moreover, parathyroid hypertrophy has been found in most cases when a careful search has been made at autopsy.⁹⁶ Regarding the character of the bone changes and their causation, however, opinion is sharply divided.

The difficulty of interpreting the physiology of certain other skeletal disorders that result in or apparently arise from renal dysfunction complicates the dispute still more. Hyperparathyroidism, caused either by parathyroid adenoma or by idiopathic diffuse hyperplasia of the parathyroid glands, may produce marked renal damage. The increased secretion of parathyroid hormone leads to increased renal phosphate excretion and, in turn, to hypophosphatemia, hypercalcemia and finally hypercalciuria.⁹⁷ Calcification of the kidney tubules, the formation of calcium stones and the subsequent complication of pyelonephritis lead, in many cases, to fatal uremia.⁹⁸ Cystine-storage disease⁹⁹ likewise causes renal damage and bony abnormalities somewhat similar to those of rickets. Few cases have been reported, and nothing is known of the biochemical alterations. Cystine deposits and cystine calculi have been found in the kidneys. In contrast to these metabolic and endocrine disturbances are certain rare conditions in which anomalies of renal function lead to biochemical and skeletal defects that are different in some respects from those frequently seen in renal insufficiency. A few cases of renal glycosuria, hypochloremia, hypophosphatemia, hypocalcemia and acidosis, usually associated with dwarfism, have been reported.^{100, 101} McCune, Mason and Clarke¹⁰⁰ suggest that this so-called "Fanconi syndrome" results from a developmental defect of the renal tubules that permits loss of glucose, phosphate and base. The chronic acidosis is considered to be the cause of the skeletal deformity. A somewhat similar disorder described in adults as well as in children,¹⁰²⁻¹⁰⁴ in which renal damage appears to be secondary to deposits of calcium in the kidney, differs from the Fanconi syndrome in presenting hyperchloremia and in the absence of glycosuria. Albright and his associates¹⁰² suggest that the primary defect is a tubular inability to secrete an acid urine, calcium taking the place of deficient base in the urine. Snapper⁹⁵ and others⁹² have re-

and during shock, cannot be prevented by dietary measures¹²⁷ and is apparently not attributable to tissue destruction or disuse atrophy.¹²⁵ It has been suggested¹²³ that this phenomenon is related to Selye's¹²³ "alarm reaction" and may possibly be due to excess secretion of the so-called "S hormone" by the adrenal cortex. It is entirely possible that similar factors are operative in some cases of renal insufficiency and account, in part, for azotemia. Certainly, the characteristic wasting is attended by mobilization of nitrogen and negative nitrogen balances have been observed in chronic renal disease.¹²⁹ From a therapeutic standpoint, it is interesting that desoxycorticosterone appears to retard the elevation of nonprotein nitrogen in nephrectomized rats.⁷³

Urea

Urea mounts in the blood following a reduction of glomerular filtration rate more rapidly than other nitrogenous substances and makes up an increasingly larger fraction of the nonprotein nitrogen. Tubular reabsorption of urea appears to be passive, increasing as the urine flow falls.¹³¹ It is not surprising, therefore, that urea retention should be prominent when filtration reduction is only moderate, since the slowing of the stream of glomerular filtrate permits a larger fraction of the urea to return to the blood by diffusion. An adequate correlation between the filtration rate and the plasma urea concentration, however, does not obtain throughout the course of renal disease.¹³¹ Indeed, the urea level may remain essentially normal until renal insufficiency is marked. This behavior apparently depends on several factors. Tubular diuresis may decrease urea reabsorption and counteract in a small way the effect of defective filtration. But it seems likely that decreased ingestion of protein, as a result of anorexia, is more important in preventing elevation of plasma urea. Moreover, it is possible that urea production is diminished.¹³²

It has been proved that urea is relatively non-toxic in the concentrations usually found in uremia.¹³³ Indeed, patients with blood urea nitrogen concentrations persistently above 200 mg per 100 cc may pursue active lives for several years. It has been suggested, however, that urea interferes with detoxification in the body and permits the accumulation of more toxic substances.¹³²

Creatinine and Guanidine

Creatinine, like urea, appears to be an end product of metabolism that lies outside the metabolic pool.³ These compounds cannot be used by the cells in any manner and must be removed from the body as they accumulate. The addition of creatinine to the blood, however, is relatively slow, and its plasma level does not rise proportionately as high as that of urea.¹³⁴ Hence, creatinine retention tends to occur only after renal disease is far

advanced and is therefore considered to have greater prognostic significance than urea. This phenomenon is possibly based, in part, on the fact that in man creatinine is excreted by tubular activity as well as by filtration.¹³⁵

Guanidine, a highly toxic compound related to creatinine, has aroused considerable interest because of studies indicating an increase of this substance in the blood during uremia that parallels the development of the symptoms.^{93, 137, 138} But it does not follow that this relation is causal, nor has it been proved that the blood guanidine even reaches a toxic level, since the methods of determining it are unsatisfactory and relatively nonspecific.

Uric Acid

The degradation of nucleoproteins in man ends in the production of uric acid, which is excreted in the urine after filtration through the glomerulus and partial reabsorption by the tubules. The details of the metabolism of this curious substance remain unsolved. It possesses unusual physiochemical properties that give it value in water conservation among reptiles and birds,⁴ but that are apparently of little benefit to man. In gout, deposits of the material in synovia and cartilage are associated with abnormalities of its excretion, hyperuricemia and arthropathy. Likewise, uric acid accumulates in the plasma during renal insufficiency, but whether this circumstance is responsible for goutlike episodes of synovitis, bursitis and arthritis is unknown.

It has been claimed that uric acid is retained in the blood during renal insufficiency earlier than any other substance and that such retention has considerable value from the diagnostic viewpoint.^{134, 135} This claim has been disputed,¹³⁹ but it appears to be true for many cases. It is of great interest that hyperuricemia may be one of the earliest evidences of pre-eclampsia.¹⁴⁰ Chesley and Williams¹⁴¹ have found that this phenomenon is caused by a reduction of uric acid clearance secondary to a decrease in the glomerular filtration rate and an increase in tubular reabsorption rather than by a change in metabolism, as others have claimed.¹⁴⁰

Glucose

Glucose is typical of the second group of substances discussed above. It is reabsorbed from the glomerular filtrate almost completely. This process of conservation is rarely disturbed even in advanced renal disease when water and salt are lost in abundance. Rarely, renal glycosuria does occur, but for the most part the reduction in filtration rate appears to outstrip the reduction in tubular activity so that the capacity for glucose reabsorption is not exceeded. A disturbance of carbohydrate metabolism, however, has been demonstrated by Linder, Hiller and Van Slyke.¹⁴² In far-advanced renal disease, an abnormal blood sugar curve was found following the ingestion of glucose. The glucose con-

is retained early in the course of renal insufficiency and has been suggested as a more reliable index of renal failure than the concentration of most other substances¹¹⁴

Magnesium, likewise, often accumulates in the blood during renal insufficiency, but it appears that the concentrations attained are never sufficiently high to evoke symptoms on the basis of its own pharmacologic activity¹¹⁷⁻¹¹⁹

NONELECTROLYTES

Most of the solid matter in solution or in colloidal suspension in the plasma is organic and nonelectrolytic in nature. These substances vary widely in complexity from the small molecule of urea to the highly intricate structures of the various plasma proteins and fats. In general, they comprise what has been termed the "metabolic pool," existing in equilibrium, like the electrolytes, with similar substances within the cells and readily available for use in various intracellular reactions. Certain substances, like creatinine and urea, appear to be end products of metabolic processes and must be removed from the body,³ whereas others are essential to the construction of more complex compounds or to the development of energy for use by cells and must, therefore, be conserved. The kidneys are important in the maintenance of the plasma composition of many of these substances either by providing a route of active excretion or by preventing their loss in the urine.

Relatively little is known of the factors that govern the plasma concentrations of most of these compounds. The methods of chemical analysis are unsatisfactory and often difficult. In fact, a relatively large residue of organic material in the blood and urine remains unanalyzed. Moreover, the intracellular reactions in which organic compounds participate cannot be examined directly. Despite this paucity of knowledge, or perhaps because of it, there has been considerable speculation regarding their activity during renal insufficiency.

In general, these compounds fall into three groups from the standpoint of renal physiology. Large complex molecules that cannot pass the glomerular filter, such as proteins and fats, do not appear in the filtrate except during renal disease. Under these circumstances protein and lipoidal substances may be lost in the urine. In addition, it appears that abnormal renal cellular activity may provoke a general disturbance in fat¹²⁰ and protein metabolism¹²¹. A second group of substances, including glucose and the amino acids, appear in the glomerular filtrate and are so actively reabsorbed that little is lost in the urine. Curiously enough, an excessive loss does not usually occur even in advanced renal insufficiency. The third category, however, composed of diffusible waste products, including urea, creatinine and uric acid, is normally excreted in

large amounts in the urine and accumulates in the blood when the filtration rate is reduced.

The retention of organic catabolites in the blood during renal insufficiency was discovered shortly after Bright's demonstration of the relation between renal disease and uremia. The hypothesis that the symptomatology of uremia is based on an intoxication by these substances was immediately developed and has continued to occupy a prominent position in discussions of renal insufficiency. But little direct and trustworthy evidence has been brought forward in support of this thesis. Each of a number of substances has been advanced as the sole cause of symptoms. More recently, emphasis has been placed on the possibility that the retention of several toxic agents is involved.^{122, 123} It is tacitly or explicitly implied in most studies, however, that the uremic syndrome arises from a toxemia. In the light of the increasing knowledge of the metabolic imbalance during renal insufficiency, this viewpoint seems oversimplified. Certainly, the serious disturbances of body water and electrolytes must play a role in causing symptoms. Likewise, it seems probable that a general disorder of all metabolic activity, arising from the abnormalities of plasma catabolite concentrations among others, is involved. In this view, the increased concentrations of such substances as urea, creatinine, phenol and guanidine are important not because of the pharmacologic action of each but because of the interference with many intracellular reactions in which they participate. For this effect, none of them need be present in the blood in toxic amounts.

Nonprotein Nitrogen

It is well known that the nonprotein nitrogen content of the plasma increases, as a rule, with renal insufficiency. This change has come to be regarded as the hallmark of renal failure, although occasionally azotemia fails to develop even in far-advanced renal disease.¹²⁴

The nonprotein nitrogen of the blood is derived from many sources, among which urea, creatinine, uric acid and the amino acids are most significant. The plasma concentrations of these compounds, with the exception of the amino acids and possibly other substances that contribute little to the total nonprotein nitrogen, depend on a balance between tissue breakdown, intracellular metabolic processes and diet on the one hand and renal excretion on the other. Thus, azotemia develops when this balance is deranged by a failure of renal excretion or by an increase in the production of nitrogenous substances, or both.

Recent studies indicate that a negative nitrogen balance develops in the presence of unusual stress.^{125, 126} Excessive nitrogen loss, which occurs during fever, after trauma or operative procedures

and during shock, cannot be prevented by dietary measures¹²⁷ and is apparently not attributable to tissue destruction or disuse atrophy.¹²⁸ It has been suggested¹²⁹ that this phenomenon is related to Selye's¹³⁰ "alarm reaction" and may possibly be due to excess secretion of the so-called "S hormone" by the adrenal cortex. It is entirely possible that similar factors are operative in some cases of renal insufficiency and account, in part, for azotemia. Certainly, the characteristic wasting is attended by mobilization of nitrogen and negative nitrogen balances have been observed in chronic renal disease.¹³¹ From a therapeutic standpoint, it is interesting that desoxycorticosterone appears to retard the elevation of nonprotein nitrogen in nephrectomized rats.⁷¹

Urea

Urea mounts in the blood following a reduction of glomerular filtration rate more rapidly than other nitrogenous substances and makes up an increasingly larger fraction of the nonprotein nitrogen. Tubular reabsorption of urea appears to be passive, increasing as the urine flow falls.¹³² It is not surprising, therefore, that urea retention should be prominent when filtration reduction is only moderate, since the slowing of the stream of glomerular filtrate permits a larger fraction of the urea to return to the blood by diffusion. An adequate correlation between the filtration rate and the plasma urea concentration, however, does not obtain throughout the course of renal disease.¹³³ Indeed, the urea level may remain essentially normal until renal insufficiency is marked. This behavior apparently depends on several factors. Tubular diuresis may decrease urea reabsorption and counteract in a small way the effect of defective filtration. But it seems likely that decreased ingestion of protein, as a result of anorexia, is more important in preventing elevation of plasma urea. Moreover, it is possible that urea production is diminished.¹³²

It has been proved that urea is relatively nontoxic in the concentrations usually found in uremia.¹³⁴ Indeed, patients with blood urea nitrogen concentrations persistently above 200 mg per 100 cc may pursue active lives for several years. It has been suggested, however, that urea interferes with detoxification in the body and permits the accumulation of more toxic substances.¹²²

Creatinine and Guanidine

Creatinine, like urea, appears to be an end product of metabolism that lies outside the metabolic pool.¹³⁵ These compounds cannot be used by the cells in any manner and must be removed from the body as they accumulate. The addition of creatinine to the blood, however, is relatively slow, and its plasma level does not rise proportionately as high as that of urea.¹³⁴ Hence, creatinine retention tends to occur only after renal disease is far

advanced and is therefore considered to have greater prognostic significance than urea. This phenomenon is possibly based, in part, on the fact that in man creatinine is excreted by tubular activity as well as by filtration.¹³⁶

Guanidine, a highly toxic compound related to creatinine, has aroused considerable interest because of studies indicating an increase of this substance in the blood during uremia that parallels the development of the symptoms.¹³⁷ But it does not follow that this relation is causal, nor has it been proved that the blood guanidine even reaches a toxic level, since the methods of determining it are unsatisfactory and relatively nonspecific.

Uric Acid

The degradation of nucleoproteins in man ends in the production of uric acid, which is excreted in the urine after filtration through the glomerulus and partial reabsorption by the tubules. The details of the metabolism of this curious substance remain unsolved. It possesses unusual physicochemical properties that give it value in water conservation among reptiles and birds,¹³⁸ but that are apparently of little benefit to man. In gout, deposits of the material in synovia and cartilage are associated with abnormalities of its excretion, hyperuricemia and arthropathy. Likewise, uric acid accumulates in the plasma during renal insufficiency, but whether this circumstance is responsible for goutlike episodes of synovitis, bursitis and arthritis is unknown.

It has been claimed that uric acid is retained in the blood during renal insufficiency earlier than any other substance and that such retention has considerable value from the diagnostic viewpoint.¹³⁹ This claim has been disputed,¹³⁹ but it appears to be true for many cases. It is of great interest that hyperuricemia may be one of the earliest evidences of pre-eclampsia.¹⁴⁰ Chesley and Williams¹⁴¹ have found that this phenomenon is caused by a reduction of uric acid clearance secondary to a decrease in the glomerular filtration rate and an increase in tubular reabsorption rather than by a change in metabolism, as others have claimed.¹⁴⁰

Glucose

Glucose is typical of the second group of substances discussed above. It is reabsorbed from the glomerular filtrate almost completely. This process of conservation is rarely disturbed even in advanced renal disease when water and salt are lost in abundance. Rarely, renal glycosuria does occur, but for the most part the reduction in filtration rate appears to outstrip the reduction in tubular activity so that the capacity for glucose reabsorption is not exceeded. A disturbance of carbohydrate metabolism, however, has been demonstrated by Linder, Hiller and Van Slyke.¹⁴² In far-advanced renal disease, an abnormal blood sugar curve was found following the ingestion of glucose. The glucose con-

centration reached a higher level than normal and returned slowly to the control value. Since no abnormality of the respiratory quotient was demonstrable, it was concluded that some factor other than a failure to burn glucose, such as retarded glycogen storage, was responsible. In the absence of renal failure the glucose tolerance was normal. This defect of carbohydrate metabolism is in line with the view that uremia arises from a general metabolic disturbance.

Amino Acids

The amino acids are also reabsorbed efficiently, and if retention occurs it apparently stems from an abnormality of liver function. Lyttle and his co-workers¹⁴³ have given intravenous injections of casein hydrolysate to children with renal disorders and have studied the rate of return of amino acids in the blood to a normal level. They found that normal removal from the blood occurred in spite of the presence of renal insufficiency. In children with hepatic disease and normal renal function, however, the removal of amino acid was greatly retarded.

In this study, it was found that the nephrotic syndrome was characterized by normal uptake of amino acids, in harmony with the work of others.¹⁴⁴ But an augmentation of amino acid removal from the blood has been observed shortly before the onset of the so-called "nephrotic crisis," with the subsequent development of hypoaminoacidemia.¹⁴⁵ The causes for the negative nitrogen balance and loss of amino acids in this situation are obscure. It appears that the parenteral administration of casein hydrolysate corrects the disturbance of nitrogen balance to some extent and apparently produces a significant reduction of fatalities due to bacteremia during the crisis.¹⁴⁶ Farr¹⁴⁴ attributes the loss of nitrogen to toxic nitrogen metabolism. It is not clear whether the loss of amino acids in the urine is a factor.

It should be understood that the methods now available for studying the amino acids of the blood are unsatisfactory and that what has been said about them has reference, for the most part, to the alpha amino acids detected by the ninhydrin method. Other methods are available for the determination of many individual acids. The use of these procedures in studies of the behavior of different acids during renal insufficiency should elicit much interesting information.

Phenols

The discovery that phenolic compounds accumulate in the blood during uremia has aroused considerable interest.¹⁴⁷⁻¹⁵⁰ These substances are believed to be derived largely from the degradation of aromatic amino acids in the intestine. Free phenols are extremely toxic, causing renal damage and central-nervous-system depression. Harrison¹²² sug-

gests that they are responsible for certain of neuromuscular phenomena observed in uremic animals. The methods used in determining the concentrations of phenols in the blood, however, are nonspecific and unreliable. The chief argument in favor of the importance of these substances in the production of uremia lies in the fact that a good correlation has been found between symptomatology and phenol accumulation. This need not imply a causal relation, however.

There is little evidence to support the view that other toxic products of intestinal putrefaction, such as indican, are of any significance in uremia.^{151, 152}

Plasma Proteins

Protein is lost in the urine throughout most of the course of renal insufficiency, probably owing to increased passage of large molecules through the defective glomerular filter, although there is evidence that diminished tubular reabsorption of protein is also at fault.¹⁵³ The character of the urinary protein complies with the view that an increase in the size of glomerular pores permits smaller species of protein molecules, particularly albumin, to escape from the plasma. When this loss is excessive, hypoproteinemia develops. It appears that urinary loss is not sufficient to account for the diminution of protein in most cases, however, and a disturbance of protein manufacture must be posited.¹⁵¹ Since protein escape is reduced by the contraction of the glomerular filter bed with progressive renal damage, hypoproteinemia is gradually corrected, and during the terminal stages of uremia, it is not a prominent feature.

The study of the plasma proteins is still in its early stages. New methods have been developed and have not yet been extensively applied to the investigation of renal disease.

Lipids

It has been shown that renal damage not only permits the escape of lipoidal compounds in the urine but also leads to lipemia and hypercholesterolemia. For reasons as yet unknown, this disturbance of fat metabolism is most profound in the presence of hypoproteinemia and may be related to it in some way. As renal failure progresses, these abnormalities regress.^{120, 154, 155}

* * *

Throughout this discussion, an effort has been made to emphasize the complex nature of biochemical disturbances during renal insufficiency. This complexity arises from the simultaneous derangement of metabolic activities of all types throughout the body and is secondary to the disorder of plasma composition resulting from the failure of the kidney to perform its regulatory functions. It is probable that the symptomatology of uremia is the result of the action of multiple

factors, among which the change in the character of the metabolic pool bulks large

The attempt to find toxic agents retained by the diseased kidney to account for various symptoms has not been fruitful. No evidence that the kidney manufactures toxic substances has been elicited,¹³⁶ and the evidence suggesting that intoxication by products of intestinal putrefaction occurs is not convincing. It may be that substances as yet undetermined play an important role, but there seems to be ample cause for symptomatology in the disturbances that have been subjected to quantitative study.

Obviously a considerable amount of work remains to be done. At present, the factual knowledge of normal processes is faulty and incomplete, and it is not surprising that a satisfactory understanding of the abnormalities has not yet been attained. As methodology improves and factual data accumulate, however, rapid strides on the conceptual level may be confidently expected.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., Editor

BENJAMIN CASTLEMAN, M.D., Associate Editor

EDITH E. PARRIS, Assistant Editor

CASE 32481

PRESENTATION OF CASE

First admission A thirty-eight-year-old Italian clerk entered the hospital because of a swelling below the right eye, which he suspected of being a "cancer."

For three years before entry the patient had noticed many small, spidery, red spots on the cheeks, abdomen and flanks. These never increased in size or caused him any concern until two months before entry, when one of these spots beneath the right eye began to enlarge. Except for this condition, the patient considered his health excellent. He had had a slight, nonproductive cough following an attack of pleurisy eighteen years previously. Since the age of nine years he had also had an occasional slight purulent discharge from the right ear. He had observed no swelling of the abdomen, jaundice, hemorrhoids, varicose veins or ankle edema. The alcoholic intake was impressive, amounting to at least a bottle of wine a day since childhood and an additional daily consumption of about a quart of whiskey and several bottles of beer for the preceding eight years. Nevertheless, he insisted that his diet was "good" and his appetite keen. The weight had remained constant for

the past seventeen years. The urine had been orange on occasion, but the stools had always been brown.

The patient was a well developed and well nourished man with fine spider angiomas over the chest, upper abdomen and flanks. Below the right eye there was an angioma 2 cm. in diameter with a slightly raised red antrum 3 mm. in diameter. The heart and lungs were clear. The abdomen was protuberant and soft, with a questionable fluid wave but no shifting dullness. The liver edge was readily palpable, extending 12.5 cm. below the costal margin in the anterior axillary line, but was firm and nontender.

The temperature, pulse and respirations were normal. The blood pressure was 140 systolic, 85 diastolic.

The blood van den Bergh reaction was 27 mg. per 100 cc. total. The cephalin-flocculation test was ++++ at the end of twenty-four hours. A bromsulfalein test showed 35 per cent retention of the dye. The total serum protein was 7.6 gm. per 100 cc., with an albumin-globulin ratio of 1.5. The urine gave a ++++ test for bile and green, blue and orange reactions for sugar on three occasions. The stools were guaiac negative.

A gastrointestinal series and chest plates were essentially negative.

Peritoneoscopy revealed a large "hobnail" liver, and a biopsy specimen was reported as showing advanced toxic cirrhosis.

The patient was discharged with instructions to abstain from alcohol and to follow a high-vitamin, high-carbohydrate, high-protein, high-calorie and low-fat diet.

Final admission (four and a half years later) The patient was followed in the Out Patient Department and apparently did well although he noticed slight swelling of the ankles at night, he had a dirty-gray color. He claimed to have restricted his drinking to about four highballs a day. A month before entry he began work as a night watchman and

felt unusually tired and sleepy. On the day of entry, he developed chills and fever while at his job and was brought to the emergency ward via ambulance. On arrival he also noted "dizziness" and swaying from side to side while walking. The right ear had recently been draining purulent material, but this was no different from many previous episodes.

The patient appeared acutely and chronically ill. He was drowsy and dozed off several times during the examination. The skin was hot and dry and showed a grayish icteric pigmentation, most marked in the exposed areas. There were numerous spider angiomas. A skin test for iron pigment was negative. The pharynx and soft palate were beefy red, with a mucous coating over the posterior portion. The right ear canal contained blood-tinged, seropurulent discharge. There were a few rales at the left base. A Grade II apical systolic murmur was transmitted over the entire precordium. The aortic second sound was louder than the pulmonic. There were shifting dullness over the abdomen and a questionable fluid wave. The liver edge was palpable 4 fingerbreadths below the costal margin. Moderate muscle weakness was apparent in all extremities, and vibratory sense in the legs was absent.

The temperature was $100\pm^{\circ}\text{F}$, the pulse 100, and the respirations 24. The blood pressure was 110 systolic, 60 diastolic.

Examination of the blood showed a red-cell count of 4,840,000, with 15 gm of hemoglobin, and a white-cell count of 20,200, with 92 per cent neutrophils. The fasting blood sugar was 190, the non-protein nitrogen 30 and the phosphorus 2.5 mg per 100 cc, the alkaline phosphatase was 6.1 Bodansky units per 100 cc, the sodium 128.4 milliequiv per liter and the serum protein 5.8 gm per 100 cc, with an albumin-globulin ratio of 0.8. The van den Bergh reaction was 5.6 mg per 100 cc direct and 10.0 mg total. The cephalin-flocculation test was ++++ in twenty-four hours. The prothrombin time was 30 minutes, with a control of 18 minutes. *Staphylococcus aureus* was grown on two consecutive blood cultures. The urine was dark amber, with a specific gravity of 1.014. There was a green test for sugar and a ++ test for bile but no albumin. The sediment contained many white cells, red cells and granular casts per high-power field.

An x-ray film of the chest showed enlargement of the heart, particularly in the region of the left ventricle and left auricle. The diaphragm moved only slightly. The lung fields were clear. There was a suggestion of small varices in the lower third of the esophagus.

An electrocardiogram showed a rate of 95, with sinus rhythm. The PR interval was 0.18 second and the QRS complex 0.08. The voltage was normal, and there was no deviation of the axis. The T waves in Leads 1 and 2 were unusually broad and rather low.

The temperature gradually returned to normal on penicillin therapy, but the pulse rate was continuously elevated, the patient frequently lapsed into a semicomatose or delirious state. The dosage of penicillin was 24,000 units every three hours for six days and was increased to 32,000 units every two hours for the remainder of the illness. A lumbar puncture showed an essentially normal fluid with normal dynamics. During the ten days in the hospital the patient gained 22 pounds, which was apparent as pitting edema over the dependent portions and increasing ascites. On the seventh hospital day a Grade II diastolic murmur to the left of the sternum was discovered. The patient was digitalized and given Mercupurin. Nevertheless he continued to gain fluid. A Prussian-blue skin test for hemochromatosis was negative in two injection sites. On the sixteenth hospital day the patient was found unresponsive, with Cheyne-Stokes respirations, and he died shortly thereafter.

DIFFERENTIAL DIAGNOSIS

DR. JAMES TOWNSEND: There is no record of a blood sugar determination or a blood Hinton test during the first admission four and a half years previously or of any test for sugar in the urine in any of the visits to the Out Patient Department between the admissions. Certain things in the clinical history are worthy of emphasis. The alcohol intake described is enormous, amounting to 6000 calories a day. Under these conditions it is improbable that the patient had a normal food intake, and he might therefore be considered a fit subject for avitaminosis. Secondly, spider angiomas were noticed on both admissions. These, if typical, are important findings, believed by many to be pathognomonic of Laennec's cirrhosis, but I am sure that they occur in other types of liver diseases, the most characteristic ones that I have seen occurred in a case of prolonged infectious hepatitis that began during an epidemic among the American forces in Italy. Thirdly, convincing evidence of toxic cirrhosis four and a half years previously was provided by the various chemical tests as well as by direct vision of the liver and biopsy. The chemical findings at the time of the final admission are consistent with a gradual progression or recent exacerbation of the cirrhosis. Fourthly, there was definite evidence of enlargement of the heart since the first hospitalization, as well as new murmurs, both systolic and diastolic, not previously described. Finally, the finding of a low serum sodium is worthy of note. There are two conditions that are usually associated with a low sodium—Addison's disease and severe dehydration. In this case there is no evidence of dehydration.

It seems to me that the following were the most significant findings in this long and rather complicated picture. A definite diagnosis of toxic cirrhosis was made four and a half years before the final entry, with evidence of progression of the disease during

the illness as shown by the ascites, the hypoproteinemia and the possible esophageal varices and of glycosuria at that time and during the final illness. Could the last finding be attributed to cirrhosis? There is a carbohydrate disturbance in cirrhosis, but — except after the injection of glucose — sufficient sugar in the urine to give an orange reaction is unusual. It would be extraordinary to have a fasting blood sugar as high as 190 mg per 100 cc. Therefore, I believe that this man had diabetes, probably of several years' duration, and that autopsy may have revealed some of the findings that are found in patients with chronic diabetes, usually in the vascular system, with the glomeruli showing changes characteristic of Kimmelstiel-Wilson disease and other vascular disturbances. The patient had a chronic middle-ear infection for many years, and the symptoms of acute illness began a month before the final admission, when he had fever and a discharge from his ear that increased on the day of entry. He was given a course of penicillin. New heart murmurs, both systolic and diastolic, were noted, with cardiac enlargement that had not been present four years earlier, and *Staph aureus* was grown on two blood cultures. He also had abnormal urinary findings, but without albumin, and a normal nonprotein nitrogen.

There seems to be no room for argument against cirrhosis of the liver. The clinical picture was quite characteristic, and I think we may assume that the disease either progressed in spite of treatment or became exacerbated during the final illness. I believe that the patient still had severe cirrhosis of the liver of the Laennec type. Could it have been some other type? This man had the triad of peculiar color of the skin, diabetes and liver disturbances. Hemochromatosis comes to mind. Tests were done for that, but they were negative. There was even a negative skin biopsy, and I doubt whether hemochromatosis was apparent clinically. In the few cases that I have seen the only characteristic finding has been severe diabetes, which is difficult to control in spite of large doses of insulin. If this man had diabetes, it was mild and chronic. I believe that he had diabetes mellitus in addition to the cirrhosis of the liver.

He also had a chronic suppurating process in the right ear, which I believe had much to do with the onset of the final illness. I should like to believe that it was the portal of entry of the *Staph aureus* that was found in the blood stream. There is considerable evidence to support the diagnosis of bacterial endocarditis because of the finding of new heart murmurs, the presence of cardiac enlargement and the progressively fatal course in spite of a fair amount of penicillin. If he had bacterial endocarditis, other areas of staphylococcal infection may have been observed in the kidneys and possibly in the liver or the brain, or almost anywhere in the body.

What shall we expect to find in relation to this ear? We are not given much detailed information. All we know is that the patient had had a discharging ear for a long time. He also had diabetes and cirrhosis and low resistance, however, and I suspect that this septic process was extending inward and that it had something to do with the later illness. I assume that he had involvement of the internal ear or that he had an abscess, possibly extradural or in the brain. He did not have meningitis, because the spinal fluid was normal. On the evidence at hand we cannot exclude the possibility of brain or extradural abscess or lateral sinus thrombosis. This is merely speculation, but these are the conditions that are apt to occur from chronic suppurating ears.

Finally, the illness was associated with a *Staph aureus* infection of the blood stream, which I believe was localized in the heart valves — certainly the aortic and possibly the mitral.

Did the patient have any other disease, such as a superimposed kidney lesion of some sort? He retained a tremendous amount of fluid during the last few days, and in that retention of fluid there may have been several elements. He probably had some degree of portal obstruction that encouraged ascites. He may have had some cardiac failure, although the clinical picture was not characteristic, as well as a kidney condition that encouraged the retention of fluids. The urine showed white cells, red cells and casts, but no albumin. There are at least three types of disease that might be found in such a case. A diffuse glomerulonephritis, which is the first type, almost always shows large amounts of albumin. The other types are the changes of intercapillary glomerulosclerosis and abscesses from staphylococcal septicemia.

The diagnoses that I suspect may be found are cirrhosis of the liver (Laennec type), diabetes mellitus, chronic suppurative otitis media, staphylococcal septicemia, bacterial endocarditis, embolic abscesses of the kidney or other organs, possible lateral sinus thrombosis, possible brain abscess and possible glomerulonephritis.

CLINICAL DIAGNOSES

Portal cirrhosis
Hemochromatosis?
Staphylococcus aureus sepsis

DR. TOWNSEND'S DIAGNOSES

Cirrhosis of liver, Laennec type
Diabetes mellitus
Otitis media, chronic suppurative
Staphylococcal septicemia
Bacterial endocarditis
Embolic abscesses, of kidney or other organs
Lateral sinus thrombosis?
Brain abscess?
Glomerulonephritis?

ANATOMICAL DIAGNOSES

Acute bacterial endocarditis (due to Staphylococcus aureus), with rupture of aortic valve

Hemochromatosis

Bicuspid aortic valve

Septic infarct of kidneys and spleen

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN Autopsy showed a number of findings that Dr. Townsend predicted. The heart was enlarged, weighing over 400 gm. The enlargement was probably due to a mild degree of aortic stenosis. There was a bicuspid aortic valve, as well as calcific deposits of a mild degree along both cusps. Superimposed on the deposits of calcium were grayish, pink vegetations — an acute bacterial endocarditis that had perforated both cusps. There was also a small focus of bacterial endocarditis on the mitral valve.

The liver weighed 1200 gm. and showed a severe hobnail type of cirrhosis. The color of the liver was pale brown, verging on orange, which is a color often seen when there are deposits of hemosiderin in the liver, and this was confirmed by a positive Prussian-blue reaction for iron. Although the presence of hemosiderin does not always mean hemochromatosis, a history of diabetes in addition to the finding of a uniformly deep-brown pancreas filled with hemosiderin makes the diagnosis of hemochromatosis quite definite. The pancreas was not extremely fibrous but perhaps more so than normal, and the color was certainly that seen in bronze diabetes, also, many of the regional lymph nodes were brown. We can assume that the patient did have hemochromatosis. We reviewed the original biopsy taken four and a half years previously, and that did not show hemochromatosis. It was a fairly adequate biopsy and revealed definite portal cirrhosis. This is an important case in relation to the pathogenesis of hemochromatosis. Most people believe that the initiating factor in the cirrhosis of hemochromatosis is the pigment — that is, the pigment stimulates fibrosis first in the liver and then in the pancreas. Another theory of the pathogenesis of hemochromatosis is that cirrhosis of unknown cause appears first and the iron from the normal blood destruction is abnormally metabolized. Deposits of iron in the liver were therefore superimposed on a previous cirrhosis. This case certainly fits in with this theory.

DR. TOWNSEND Did the other endocrine organs, such as the adrenal glands, show hemochromatosis?

DR. CASTLEMAN No. The involvement was not so diffuse as that in the usual cases of hemochromatosis. Quite possibly it was not present long enough.

DR. TOWNSEND This is probably why the patient's skin had a queer color. He was not given the clinical skin test?

DR. CASTLEMAN Not by the injection method. It is possible that the biopsy might have shown a

Prussian-blue reaction. The kidneys contained hemorrhagic septic infarcts.

DR. TOWNSEND The kind that occurs with *Staph. aureus*?

DR. CASTLEMAN Yes. Two small infarcts in the brain accounted for most of the cerebral symptoms.

DR. TOWNSEND Was there any local disease around the ear?

DR. CASTLEMAN No, there was no severe involvement of the middle ear, and no sinus thrombosis.

CASE 32482

PRESENTATION OF CASE

A thirty-four-year-old unmarried woman, a typist, was admitted to the Neurological Service because of severe pain in the right leg.

Six months before admission the patient had been operated on because of prolonged excessive vaginal bleeding of two months' duration, there had been three episodes of severe low abdominal pain during this period. At operation both tubes and bloody cysts of both ovaries were removed. Fifteen days after operation a sudden, severe right-sided "sciatica" had occurred, after which the pain had been constant. It ran from the hip into the right leg, down to the heel and sometimes up the spine. Between the severe, sharp bouts it was present as an ache. At the time of the menstrual periods, the pain was worse. It was not aggravated by coughing, sneezing or straining. X-ray studies of the chest and hip were negative. After operation there was no intermenstrual bleeding. The periods were regular and extremely painful. The pain was largely in the left lower quadrant. The distress made the patient nervous and apprehensive, and she was often nauseated. She had lost 5 pounds in weight.

Physical examination showed an undernourished and anxious woman. There were tenderness and voluntary spasm in the left lower abdominal quadrant. The right leg was slightly weaker than the left, and straight-leg raising was limited to 45° on that side. The cervix was large and soft. The uterus was retroverted, partially fixed and enlarged. Any movement of the cervix or uterus caused severe pain. A cystic mass was palpable in the posterior cul-de-sac. Rectal examination confirmed the fixation of the uterus and the presence of a hard mass off the left side of the cervix and uterus.

Examination of the blood revealed a red-cell count of 4,010,000, with a hemoglobin of 12.6 gm., and a white-cell count of 8600. The urine gave a + test for albumin, and the sediment contained 3 to 30 white cells and 1 red cell per high-power field. The sedimentation rate was 2 mm. in fifteen minutes, 7 mm. in thirty minutes, 14 mm. in forty-five minutes and 19 mm. in sixty minutes. X-ray studies of the chest, spine and kidneys were negative. In the intravenous pyelogram the lower ureters diverged

somewhat laterally, and there was pressure on the superior margin of the bladder, probably from an intrapelvic mass, which could not be outlined.

An operation was performed on the fifth day.

DIFFERENTIAL DIAGNOSIS

DR. MARSHALL K. BARTLETT There are a number of points of interest in this history. In the first place, of course, one would like to know the nature of the ovarian cysts removed six months before entry. What kind of lesion could have caused the surgeon to remove both tubes and bilateral ovarian cysts in a thirty-four-year-old unmarried patient? Simple cysts of the ovaries might contain bloody fluid and give the type of vaginal bleeding that this patient had. The duration of trouble before the first operation was brief, but there was no previous mention of dysmenorrhea. We know that there were three episodes of severe pain low in the abdomen during that period. Were the cysts endometriosis? That certainly comes to mind promptly in an unmarried patient of thirty-four who has menstrual difficulties. Were they malignant cysts? I think that we can go far enough to say that if they were malignant the fact was not recognized at the time of operation, otherwise, that type of procedure would not have been done. Certainly, removal of the cysts and the tubes would not be considered adequate surgery if the lesion had been recognized as malignant. I do not see how we can decide the exact nature of the cysts.

The next thing of interest is the onset of severe right-sided "sciatica" fifteen days after operation. Was that due to an underlying lesion in the pelvis? It is hard for me to accept that as the principal cause. It seems to me that if this had been a development of a process in the pelvis the onset would have been more gradual and more insidious. The distribution suggests involvement of the sacral nerve roots. The pain was continuous, with acute exacerbations throughout the interval, until admission to the hospital. It is stated that the pain in the back and leg was worse at the time of the periods. I cannot attach too much significance to that, because almost every patient with backache asserts that it is worse at the time of a period. I am therefore inclined to discount the statement.

X-ray studies of the chest and hip were negative. The periods were regular, with no further intermenstrual bleeding. In other words, normal ovarian tissue must have been left behind at the operation—at least enough so that the patient was able to have regular periods. The periods were painful. Again, it would be interesting to know how much dysmenorrhea she had had before the first operation. In any case, in the interval between the two operations, the periods were painful, and the pain was chiefly in the left lower quadrant. On admission it was noted that the right leg was slightly

weaker than the left. One would like to know if that muscle weakness was generalized, involving all the muscle groups, or perhaps limited to certain muscle groups. Certainly at that time there was a pelvic lesion of some kind, with a palpable mass. Was the original lesion a pelvic inflammation and was this episode a recurrence? It seems unlikely to me, because the tubes had been taken out at a previous operation for pelvic inflammation. That should have cured her. Were the cysts that were removed simple ovarian cysts? Again, it seems to me that the patient should have been cured by the first operation and should not have gone on to develop a further pelvic lesion, or at least not so promptly. Were they malignant ovarian cysts, with recurrence in the pelvis? I do not see any way that I can rule that out. She was rather young, which is somewhat against it. I think that if the disease had been recognized as malignant she should have had more extensive surgery at the original procedure.

Could recurrence of malignant disease in the pelvis cause the back pain? I think that it could on the basis of metastases. We have no x-ray evidence to support that. Could this process in the pelvis have been endometriosis? Certainly, the patient was in the right age group. She was nulliparous and it seems like a good bet. If the first operation was done for that reason, a conservative procedure would be justified in a patient of her age, although the removal of the tubes, of course, would not be desirable. It would account for the recurrent process in the pelvis with dysmenorrhea in the interval between operations. Can we explain the back pain on that basis? I cannot remember seeing a patient with back pain of this type due to endometriosis. I am rather inclined to believe that the back pain had no relation to the process in the pelvis. As my first diagnosis, I shall put endometriosis as the cause for the underlying disease, with a malignant lesion in the pelvis as a second choice.

DR. TRACY B. MALLORY Dr. Ingersoll, you were present at the operation, will you describe the findings?

DR. FRANCIS M. INGERSOLL I was not present, but I heard about it. The patient had been operated on previously. At operation the surgeon found what can best be described as a "frozen pelvis"—so frozen that operation was a difficult technical procedure. Behind the sigmoid on the left side, there was a cystic mass and the sigmoid mesentery formed one of its walls. In freeing up the sigmoid three holes were made in it, which I mention simply to demonstrate how difficult it was to free the sigmoid and straighten out the situation in the pelvis. There was a cyst not related to the ovary on the right side. Since it was apparent that an extensive endometriosis was involved, the surgeon removed the uterus and the remnants of the ovaries and did a colostomy, exteriorizing the sigmoid.

CLINICAL DIAGNOSIS

Endometriosis
Pelvic inflammation?
Carcinoma of ovary?

DR. BARTLETT'S DIAGNOSIS

Endometriosis

ANATOMICAL DIAGNOSIS

Endometriosis.

PATHOLOGICAL DISCUSSION

DR. MALLORY The specimen that we received in the laboratory showed extensive endometriosis of the remaining fragments of the two ovaries and of the posterior surface of the uterus. There is very little doubt that the wall of the sigmoid would have shown the same process if we had received a specimen from it. These cases of endometriosis involving the sigmoid often make a difficult surgical problem. In a certain number of cases the surgeon has mis-

taken the lesion for a primary carcinoma of the bowel and has done extensive resection. In cases in which the lesion has been correctly diagnosed at operation, it has frequently been possible with a colostomy to tide over the temporary intestinal obstruction, perform a surgical castration and later take down the colostomy and find that the intestinal obstruction has been relieved. The endometriosis atrophies spontaneously once the ovarian function has been destroyed.

DR. BARTLETT Do you know what caused the pain in the back?

DR. HOWARD ULFELDER The patient is much better, but of course she has been on bed rest since the operation.

A PHYSICIAN Is it possible to explain the pain on the basis of pressure on the ureters?

DR. MALLORY It was impossible at operation to recognize either ureter. Both ureters were buried in scar tissue and may well have been involved, although that would have been an unusual reference of pain, would it not?

DR. ULFELDER I should think so.

INCREASE IN MORBIDITY DUE TO DIPHTHERIA

A NOTE from the Massachusetts Department of Public Health, appearing elsewhere in this issue of the *Journal*, indicates that there has been a marked increase in diphtheria in Greater Boston during 1946, a considerable portion of which has occurred since September 1. In recent years diphtheria has become a rare disease in Massachusetts, and during the past decade many physicians have not even had the opportunity of studying clinical cases during the time of their medical-school training. Control of this infection has been attributed largely to immunization programs that have been universally adopted throughout the Commonwealth.

Preliminary laboratory reports have demonstrated that the diphtheria bacilli recovered from many of the cases in the Greater Boston area during September were the gravis type. Studies published in 1944 suggested that such strains are associated with a malignant variety of clinical diphtheria with a considerable proportion of infections of the so-called "bull-neck" variety,¹ but this observation has not been confirmed in Massachusetts.² Thus, in a recent outbreak from which the gravis type of diphtheria bacilli was recovered, the majority of cases had an extremely mild clinical course. This confirms the conclusion of Frobisher³ that clinically severe diphtheria is only irregularly associated with the gravis type of organism, which is not of itself sufficient to cause malignant diphtheria.

In Canada recent statistical studies have indicated a change in the age distribution of diphtheria, and in one reported epidemic it was found that 45 per cent of the cases occurred in persons over fifteen years of age.^{4, 5} In Massachusetts, during 1945, 44 per cent of the cases were in the same age group, and in the three preceding years, at least 45 per cent of all reported cases occurred in persons who were ten or more years old.²

Another interesting observation noted in the Canadian report is that 250 (24 per cent) of 1028 diphtheria cases occurred in persons who had been completely immunized or had negative Schick reactions. It was also found that 9 persons developed diphtheria who had a circulating antitoxin level in excess of the Schick-negative level of 0.004 unit per cubic centimeter, that these persons actually had diphtheria is indicated by the fact that they developed a significant increase in antitoxin titer after convalescence. In another study, however, a comparison of the incidence rates in two groups—one composed of Schick-negative persons and the other of unimmunized persons—showed that the rate in the Schick-negative group was one tenth of that in the unprotected population. In a preliminary tabulation of 99 cases recently reported in and about Boston, it was found that 25 persons had been previously immunized, 5 of these patients having received their inoculations since 1944 and 15 since 1940.

The present tendency toward a shift in the age distribution of diphtheria cases and the occurrence of the disease in a large proportion of immunized persons are of particular significance when consideration is given to the question of booster doses. For several years, the Massachusetts Department of Public Health has advocated booster doses for children at the time of entering school. In the Greater Boston area, in the face of the increased incidence, it is now recommended that booster doses be administered to all preschool children if two or more years have elapsed since the time of the initial inoculation—on a community basis, it is perhaps more practical to administer a booster dose of toxoid than to do Schick tests and to inoculate those with a positive reaction. Furthermore, boards of health have been advised to intensify efforts at maintaining a high proportion of immunized children. It seems likely that the relative freedom from cases of diphtheria during the past few years has resulted in a relaxation in efforts in this direction. It is apparent, however, that the percentage of immunized persons must be high to prevent the occurrence of cases when the diphtheria organism is introduced into the community. Diphtheria seeks out the unimmunized!

GIVE THE INTERN HIS DUE

A LETTER published elsewhere in this issue of the *Journal* expresses views on the relations existing between staff physicians and interns in private hospitals. According to these observations the visiting physician considers the "lowly intern as an ornate figure in white that the hospital has hired and stationed as a silent sentry."

The burden of this argument is that the intern is not allowed to help in the care of the visiting physician's private patients except for a certain amount of humble routine work-up, that he is by-passed and ignored when any real responsibility is entailed and is, indeed, "a superlative and superfluous hospital attaché, who must of necessity be allowed to complete his requirements for licensure."

The remedy, our correspondent believes, is for the visiting physician or surgeon to treat his intern with greater respect and to consider him a junior colleague who has his own contribution to make and who will repay the confidence of his senior a hundred-fold in co-operation and in eagerness to be of service. Given opportunities to draw on the accumulated experience—perhaps even the wisdom—of his staff physician, the intern will respond with the latest scientific facts acquired in the halls of academic learning, as well as with a loyalty that will be reflected in improved hospital functioning.

It is surprising to learn that there are presumably up-to-date hospitals anywhere in the country that can pretend to function properly with their interns marking time as superfluous attachés. We hope that there are fewer in existence than our informant believes, and that there are not many practitioners of medicine or surgery who dare to assume full responsibility for hospitalized patients without the complete co-operation of an efficient resident staff. It had not occurred to us that such teamwork could be lacking anywhere to any appreciable extent.

There was formerly an era in which the bulk of medical knowledge was in the possession of the practitioner, who, according to his characteristics, was gracious or otherwise to his hospital interns. Today the shoe comes closer to fitting the other foot: it is the unco-operative attending physician who runs the risk of being by-passed by his house staff if he does not recognize and appreciate the services that are usually available to him and can hardly be obtained otherwise.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE TO SURVEY MALPRACTICE INSURANCE IN MASSACHUSETTS

All those who have not as yet completed and returned their questionnaires regarding medical malpractice insurance are requested to do so *immediately* in order that the facts can be made available to the committee for study. Obviously, all information obtained from the questionnaires will be held strictly confidential.

This is the most comprehensive survey of this type undertaken by the Massachusetts Medical Society, and it is hoped that a 100-per-cent return can be approached.

CARL BEARSE, *Chairman*

A HUNDRED YEARS AGO

It has long been an important problem in medical science to devise some method of mitigating the pain of surgical operations. An efficient agent for this purpose — inhalation of ethereal vapor — has at length been discovered. The process is obviously adapted to operations which are brief in their duration, whatever be their severity, and it may hereafter prove safe to administer it for a length of time and to produce a narcotism of an hour's duration. — We learn that a disgraceful fight took place on Sunday noon last between the Freshmen and medical students of Dartmouth College. It took place as they were leaving the church. — We apprehend that rectum bougies are not resorted to as frequently as they might be with striking manifestations of advantage to the patient. There is a fashion to be followed in the treatment of chronic diseases as well as in the cut of a coat. The surgeons of thirty years ago derived much more assistance from these very instruments, though of inferior manufacture, than their successors of the present day. — It is spoken of as a matter already settled that Dr Wm Lawrence of Boston, who has lately returned from Europe, has purchased the old Medical College in Mason Street which is to be fitted up for an Infirmary for children and infants. — On Wednesday last, the new edifice of the Medical College near the Massachusetts General Hospital in Grove Street was formally opened by an address from the President of Harvard University, who was particularly happy in his remarks upon the social position of medical practitioners, their duties, and their philanthropic exertions. Every person present must have been gratified with his observations, clothed as they were, in beautiful language. — If students of medicine are not well taught in this age, there must be some defect in themselves. It is a subject of perfect surprise to us that a single stupid fellow can be found in a lecture-room or office, surrounded as he must be continually by an atmosphere of science. — A boy aged 7 years received a wound between the 7th and 8th ribs by a thrust from a narrow but long-bladed knife. Three weeks and four days from the accident, he was taken with a sudden and fatal syncope. A cicatrix of the size and form of the knife-blade was found on the pericardium. There was an opening in the anterior coronary artery. The patient would have recovered perfectly if sloughing of the coronary had not taken place. Such cases do recover in all probability. We hear of cases where buffaloes have been killed, and rifle or musket balls found lodged in the substance of the heart, having entered a long time previous to death. — A slave recently died at Frankfort, Ky., at the age of 112 years. When 84 years of age, he married his fourth wife, and raised a family of 7 children. — Another important discovery has been

made in the manner of preparing gold for dental purposes. Dr Charles T Jackson, a gentleman who takes the first rank in chemistry, has prepared pellets of pure gold, almost as flocculent as wool, which only require a slight degree of manipulation to fit them to the ragged interior of a tooth, without pain, and with so slight a pressure as to make no disturbance in the region. Those who have borne the heavy pressure of the dental operator's punches and the fatigue of being belabored scientifically to save a few diseased teeth will welcome the new process with marked pleasure and interest. — An Aesculapian Society, entirely made up of medical students attending lectures in New York has commenced weekly sessions for the season. — Extracted from the *Boston Medical and Surgical Journal*, November, 1846

R. F

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

DIPHTHERIA ON THE INCREASE

Recently the Boston Health Department, in a letter addressed to physicians in Boston, pointed out that there has been an increase of diphtheria cases in that community. A similar and more striking rise has been noted in the adjoining community of Somerville. Diphtheria case rates for the two cities since 1940 are shown in the following table

YEAR	BOSTON	SOMERVILLE
1940	2 075	9 786
1941	2 075	2 936
1942	2 075	7 829
1943	4 670	17 616
1944	6 486	45 998
1945	5 967	20 552
1946 (8 months)	9 470	26 424

The case rates are per 100,000 population, based on 1940 United States Census

Since January 1, 1946, a total of more than 161 cases have been reported in the Greater Boston area, and 79 of these have occurred in Boston and Somerville during September and the first eleven days in October. It is expected that cases will continue to appear at an increased rate in this area until the effect of intensified diphtheria immunizations will have become manifest. The letter suggests that physicians bear in mind the possibility that diphtheria may occur more frequently now than it has in the past. Delay in diagnosis and tardy administration of antitoxin have been factors in the fatal outcome of several cases.

The increased incidence has been called to the attention of all boards of health in the Greater Boston area, with the recommendation that diphtheria immunization programs be strengthened. Booster doses for children previously immunized are being suggested in Boston, Somerville and the adjoining communities.

It is impossible to predict the area in which the disease will appear next. For this reason each community in the Commonwealth is being warned to take stock of its diphtheria immunization program, with immediate steps to forestall a similar rise in prevalence. The regular immunization program is as follows:

- 1 Primary immunization of all children in the first year of life—three doses of diphtheria toxoid (0.5, 1.0 and 10 cc.) Any children not immunized then should be given toxoid at the earliest opportunity.
- 2 A booster dose (0.5 cc of toxoid) at entrance to school if primary immunization was done more than two years previously. The same booster dose for children in grades up to high school who did not receive a booster dose on entrance to school in previous years.
- 3 If high-school children or adults are to be immunized a Schick test should be performed. Susceptibles should be given toxoid in divided doses, beginning with 0.1 cc. Routine booster doses are not recommended for adolescents and adults. Combined diphtheria-pertussis and combined diphtheria-tetanus immunizing agents can be used for primary immunizations and for booster doses. These products are not yet available through the department.

In the present emergency it is recommended that a booster dose be given to all preschool children if more than two years has elapsed since primary immunization.

CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS UNDER THE PROVISIONS OF THE SOCIAL SECURITY ACT

CLINIC	DATE	CLINIC CONSULTANT
Salem	December 2	Paul W. Hugenberger
Haverhill	December 4	William T. Green
Lowell	December 6	Albert H. Brewster
Greenfield	December 9	Charles L. Sturdevant
Gardner (Worcester subclinic)	December 10	John W. O'Meara
Springfield	December 10	Garry deN. Hough
Brockton	December 12	George W. Van Gorder
Fitchburg	December 18	Frank A. Slowick
Hyannis	December 19	Paul L. Norton
Worcester	December 20	John W. O'Meara
Fall River	December 30	David S. Grice

Physicians referring new patients to clinic should get in touch with the district health officer to make appointments.

MISCELLANY

NOTE

The appointment of Dr. Hugo Muench, a former staff member of the International Health Division of the Rockefeller Foundation and professor of biostatistics at the Harvard School of Public Health, as head of the Department of Biostatistics, was recently announced by Dr. James S. Simmons, dean of the School. Dr. Muench is also assistant dean.

FURTHER EVIDENCE CONCERNING THE DANGERS OF DEMEROL

An editorial in the August 8 issue of the *Journal* called attention to the dangers of addiction following the use of Demerol, an article by Paul De Kruif in the June issue of *Reader's Digest* notwithstanding. Further evidence of the habit-forming possibilities of the drug is given in a letter "Experience with Demerol in Europe," by Dr. Max Samter, of Chicago, which was published in the September 28 issue of the *Journal of the American Medical Association*. It is repeated below to re-emphasize the dangers that may result from the use of this drug.

To the Editor—The following observations may be of interest to you with regard to the controversy between Dr. C. K. Himmelsbach, Chicago, Mr. H. J. Anallinger, Washington, D. C., and Paul de Kruif, Ph. D., Holland, *MICH. (THE JOURNAL, September 7)*.

In the spring of 1945 I acted as liaison officer between First Army Headquarters and a central "German Sanitary Staff" established temporarily to maintain the function of the large number of captured German medical installations. Repeated inspections of hospitals and numerous trips throughout the occupied area gave me an opportunity to become familiar with administrative and technical experiences and difficulties encountered by the German army.

A tragic accident led me to investigate the use of Demerol by the medical department of the German units then under our control. Allied troops which had opened a medical depot found a large stock of an alcoholic preparation of Dolantin (the German trade name for Demerol) mistook it for a beverage and drank numerous bottles, a large number of casualties resulted.

Consultation with German medical officers and pharmacists revealed that the staff had at this time 40 cases of known Demerol addiction in its files; that furthermore, a large number of hospitals had abandoned its use for this reason. It is interesting to note that in Germany too it had been assumed for some time that Demerol was less addicting than morphine—a theory which had been revised by the spring of 1945.

Subsequently I was called repeatedly by military government officials to examine cases of Demerol addiction in civilians. I remember 1 instance which illustrates convincingly the danger of the drug. A physician addicted to morphine submitted twice to treatment. After the second treatment he was advised to try Demerol and developed within three months an addiction to the substitute. During this period he performed an abortion and was committed to a sanatorium for clinical study. After several weeks an attempt to withdraw the drug was made; he developed no symptoms of withdrawal. It was suspected therefore, that he had managed to obtain considerable quantities of the drug. Careful isolation revealed not only that his wife in weekly visits had issued Demerol to him but that she herself—after having taken the drug once or twice as a sedative following her husband's confinement—had become a Demerol addict.

Although the case histories on pages 43 and 44 of the September 7 issue of *THE JOURNAL* contain convincing evidence against Paul de Kruif's statement it might be helpful to add these experiences to the warning.

MAX SAMTER, M.D. Chicago

CORRESPONDENCE

THE HOSPITAL INTERN

To the Editor—Everyone concerned in the patient-doctor-hospital relation stands to gain by a more cordial affinity between staff physician and intern. The visiting physician seems to have become inured to the lowly intern as an ornate figure in white that the hospital has hired and stationed as silent sentry. Instead of taking full advantage of an enthusiastic scholar fresh from the portals of medical learning, the intern is by-passed in the doctor's care of private patients and completely deleted from their management. Both are the losers in such an aloof and lowly arrangement. Hence the intern's year often passes without the establishment of close contact with the physician, for which he yearns and is justly entitled. He is allowed to pursue his tenure in white as a superlative and superfluous hospital attaché, who must of necessity be allowed to complete his requirements for licensure.

One junior colleague's choleric comments aptly reflect a general attitude. In being brushed aside by the doctor and patient as well, he sputtered "Nuts to them! If I'm not good enough for him or his patient, I'll sit my year out until I'm good enough for patients of my own." And he quickly added, "He can do his own scout work, he'll not get any more out of me than I have to give."

The intern is in a logical position to lighten the load of routine for the staff physician's hospital practice. For example, a convenient plan, followed by some, is to make the acquaintance of the intern at the beginning of his month on the service. During a friendly chat the intern is made cognizant of one's type of practice and exactly what is expected. He is made to believe that the doctor's success is, in part, directly dependent on him. As a junior partner, his ability is equally important to the older man's skill in patient management.

One method of giving the intern concrete information is handing him at this time a small card on which are recorded routines, orders and special idiosyncrasies that the staff man may have. Such a fraternal display of friendliness will win over any intern to his staff man, making him a willing understudy and servant. After such an initial relation the intern takes a personal interest and responsibility in each patient.

He is given the information necessary for leaving initial orders should the chief be unavailable, he calls for special orders and advises of the patient's admission status.

Added to this time-saving factor of relieving the staff man of admission orders are meticulous work-ups and accurate diagnoses. By thus taking the intern under his wing, the physician ensures these, his understudy does not wish to have faith broken in him when once it has been entrusted. Instead of a *laissez faire* attitude in his intern, the chief will note a thorough, conscientious one with precision in examinations. The intern may find items that the staff physician, in the hurry to get the patient hospitalized, has casually overlooked — physical findings of inestimable value in the case or precautionary measures that may obviate complications. In reality, an attending man's reputation lies in the band of the intern. It is enhanced by the loyal junior, whose enthusiastic remarks to the patient regarding the excellent care his doctor renders ensure respect and reliance.

Hospital rounds can be expedited by the intern. Nothing is more flattering to the intern than to have his senior walk up on the floor and ask, "How are our patients, today, Doctor?" After this show of complete confidence that the intern has seen his patients and taken a personal interest, the response will be prompt. A recital of important changes or any complications needing the physician's special care will be on the tip of his tongue. Or if all is well, he will say, "Mrs. so-and-so is doing beautifully. If you are in a hurry she need not be seen today."

While in medical school, the intern learned his clinical medicine at the feet of astute professors. Their diagnostic acumen and teaching finesse firmly implanted didactic facts in his mind. He knelt at their feet four long years, listening to the masters and longing to emulate their skill. On entering the hospital he realizes that much of his knowledge is theoretical. He is anxious to see and treat patients and to prove from experience — theory is fact. He looks appealingly to the visiting staff to be his teachers. His fire for knowledge, however, may be deplorably smothered by the cold-shouldering staff man, who assumes a "better-than-thou" attitude and treats him like something akin to a floor mat.

The doctor may appropriately take his superior place as clinical instructor. The intern is crying for teaching. He considers his internship worthwhile if an occasional chief drops a few pearls from the treasure chest of experience. And it is not beyond the realm of possibility that the junior will be able to reciprocate with a few kernels of gold — nuggets recently pocketed in medical school and facts that may be useful in practice. New therapeutics are fostered by interns and residents, as well as tried and proved by them.

In payment for instruction, the intern will dig through the cumulative index for some article that his chief would like and will abstract it for him. He will graciously spend hours in diligent search for the latest treatment of a patient with chronic arthritis.

Psychotherapy, if indulged at all, can devour the lion's share of any doctor's time. In fact, time is so limited on hospital rounds that such therapy is prohibitive. Either it is deleted from the patient's care or a psychologist is called in. Here the loyal intern can shine. It would be sheer naïveté to allow an intern to approach the nervous patient without previous introduction and instruction by the patient's family physician. But after such a status is attained, the "man in white" can render suave, persuasive psychotherapy by proxy for his chief. He can give patients encouragement and inspire confidence to hasten recovery and can thus save many hours of tedious tongue trilling, at the same time giving the patient an added service that not otherwise would have been received.

If a practice is a bit too large for one man to handle and a new man is needed, a fertile field from which to choose an aide comprises the young, red-blooded, hospital interns. And there is no better way to select one than to observe various interns in their care of patients. By permitting them the freedom an assistant enjoys, the staff man sees how responsibility is borne. In this way a partner may be chosen who clicks with colleague and patient. Meanwhile, the heavy burden of routine is lifted from the senior man's shoulders, his attention can be devoted to critical patients.

A pet peeve of the junior man in the operating room is the "eager beaver" surgeon — the one in such a mad rush to earn his first million dollars that he never allows the intern

to do anything but bold retractors or get out of his way. The surgeon believes that the preoperative and postoperative care of his patients is sometimes not just what it ought to be, perhaps there is a reason. If he permits the intern to consider himself an integral part of the surgical team, not ornament or a modified scrub nurse, he will soon note a remarkable improvement in the intern's interest in the postoperative course of patients.

Whenever the intern performs a procedure, minor though it be, he tacitly assumes that the patient is his own. He did something for the patient, therefore, he is obligated to care for his patient, and he is appreciative for the surgeon's generosity. He repays by close watch over postoperative patients. Menial chores are cheerfully performed, intravenous injections gladly given, dressings changed and wounds overserved with special care, since one of his own sutures may have gone into the bandiwork of that operation.

The intern does not ask for the surgeon's knife, but mere for an opportunity to learn a little surgical technique and the privilege to get the feel of things at the operating table. The chance of tying a few knots, snapping on hemostats, closing skin incisions and performing minor procedures under supervision. Such small gestures of confidence in the intern do take a little extra time on the part of the surgeon. But the time is well invested. It will pay big dividends in the care of surgical patients.

Small favors shown the intern not only will make for better intern training but also will simultaneously lighten the load of the staff doctor. The loyalty of the intern to his staff man and hospital will be reflected in more pleasant and more efficient hospital management. Most important, the patient will reap rich rewards in greatly improved hospital care and his esteem for doctor, intern and hospital will increase accordingly.

LIEUTENANT J. DE WITT FOX, M.C., A.U.

Brooks General Hospital
Fort Sam Houston, Texas

INTRODUCTION OF DIGITALIS INTO NORTH AMERICA

To the Editor: A New Hampshire physician first used *Digitalis purpurea* in North America. Hall Jackson (1735-1797) lived in Portsmouth and was well known in New England. His father, Clement Jackson, was a doctor, and from him Hall received his early medical education. For three years he attended lectures in London at the public hospitals and made many friends there. At that time his principal interest was in smallpox. He returned to the colonies, and in 1766 he was called to Boston because of a smallpox epidemic. Later he opened a smallpox hospital on Hensell's Island. Five days after the Battle of Concord he offered his services in raising a company of Minute Men. On June 19, 1775, he was again summoned to Boston to take care of the wounded from the Battle of Bunker Hill, and he later became surgeon of a regiment that fought through the Ticonderoga Campaign. In November, 1775, he was appointed chief surgeon of all New Hampshire troops in the Continental Army, with the rank of colonel.

His interest in digitalis dated from the reading of William Withering's treatise, which he had received from London. Enthusiastic over the results that Withering had obtained, he sent to London for some of the powdered leaf and used it on his own patients. His results were so good that he wrote to Withering to tell him. Withering responded by sending him some of the seeds to be planted in New England. He suggested that the seeds be sent to other physicians in the state.

Jackson's first letter to Withering is now in possession of the Royal Society of Medicine, London, whose librarian, Miss G. F. Home, has kindly allowed its use in this note. It reads as follows:

Portsmouth, New Hampshire
North America
February 9, 1781

Sir,

Your inestimable treatise or account of the Fox glove and its medical uses, with practical remarks on dropsy, and other diseases, has found its way to this remote part of the globe. It must greatly add to the satisfaction that daily arises in your mind, on seeing so many

distressed fellow-mortals relieved by your personal advice, and administrations, to reflect that thousands at the most distant ends of the earth, are wishing to offer their tribute of gratitude for your indefatigable endeavours for the good of mankind

The gentlemen of the Society of Medical observations, and enquires, in London, the ingenious and worthy Doctors, Percival and White, of Manchester, with many others, of this day, in England, will never know how much the world is indebted to them for their publications, not only the present age, but generations yet unborn will bless their memory

There is no disorder more prevalent in this country than dropsy, our summers are extremely hot, our winters intensely cold, only two of the spring and fall months may be called temperate, our days in the winter are short, consequently our labouring people work but a few hours, the remainder of the time is spent in a sedentary, idle manner, and too often in an immoderate use of spirituous liquors. Our lumber trade to the West India Islands, returns in large quantities of rum and Molasses of the latter is distilled amongst us an inferior, cheap kind of rum, which is evidently unwholesome, it is generally used immediately from the still, it has an empyreumatic taste, and is wholly destitute of the mildness of rum that has undergone agitation at sea, and a few months age, a common labourer may receive five quarts of this new, strong, and fiery spirit, for a short day's work, from this plenty and cheapness the use is too general, and immoderate, and it is a just observation that those who indulge too freely in the use of spirits, are least anxious for substantial food. Their appetites are pallid, the solids weakened, the fluids irritated, and increased, obstructions formed, and dropsies become frequent. As yet no specific reason has been found, but in most cases, after a longer, or shorter time, the disease has proved mortal. Life in many cases has been prolonged to a considerable length of time by repeated tapping, but this has generally been with female subjects, where the disorder was of the encephaloid kind. Our remedies in general, have been such as are used in Europe, in like cases. The squills have been considered as the most powerful diuretic, and mostly depended upon, and some few have been relieved by their use, where resolution has been strong enough to preserve against the nauseating effects thereof

I have taken your treatise in my pocket for six weeks, I have shown it with the incomparable, accurate, and elegant drawing, to all my acquaintance within twenty miles, but no one can recollect of ever seeing any of its kind, in America, I am persuaded however, that it would arrive to sufficient maturity in this country, but attentive cultivation as our natural productions in general, are much the same as those of England, with this difference, the wood of our large trees is not so compact and hard, our fruit trees, nor the fruits, so large, smooth, as those of the same kind, in Great Britain, our plants and herbage in general are a degree, or two, inferior to those in England, planted in equal good soil, and cultivated with equal attention, chamomile will not flower in this country, tho' I have seen, in a very favourable season, a few scattered single-flowers, in a large hed. These remarks are from my own observations, having spent the year 1762 in England for the advantage of medical improvements

I have the honor of being acquainted with John Lane, Esq., Merchant in London, to him I have sent for a small invoice of medicines, I have directed a small quantity of *Fol. Digitalis Purp. Siccat.*, also some of the powder, and seeds, but I greatly fear they have not as yet become articles of the shops, in London, would I be so fortunate as to obtain (to the care of Mr Lane) thro' your influence, and direction, a small quantity of the genuine seed, the plant should be most attentively cultivated, most carefully prepared and as opportunity will not be wanting to administer it, the most accurate observations and remarks, on its operation, and effects, shall be noted, and if you will permit me the honor, shall be communicated to you, for any further satisfaction, or remarks, you may wish to make on this truly valuable discovery

And now Sir, I should be most painfully embarrassed for an apology in troubling a gentleman of your character with so lengthy, and uninteresting a letter, without the least personal knowledge, or the remotest introduction, was I not assured that where so much merit, and good-

ness obtains, an indulgent candour will not be wanting toward one who is sincerely desirous [sic] of doing all the possible good, in the narrow sphere in which providence has placed him, and hoped not altogether from those motives that too often actuate the generality of mankind

I am Sir (tho' unknown) with the utmost veneration of respect
Your most obliged, most obedient

HALL JACKSON

P S I have directed to be sent me two or three sets of your account of the Fox-glove, for the purpose of dispersing them. Also your *Scarlatina anginosa*, outlines of Mineralogy, and anticipate with great pleasure your proposed Botanical Arrangement. Hope it will be published before my directions are completed and sent out from London. The extremes of heat and cold in this country may be judged from the following

The Thermometer, Fahrenheits' scale stood as followeth

Portsmouth 1785	July 5th	83°
	15th	75°
	30th	80°
August from the 15th to 30th		80°
1786 January — 15 to 19		8° below 0

N B The Thermometer was placed in the open air, and the observations made at noon

The text of Withering's reply to Jackson's letter is not available, but Jackson quotes from it in a letter to Ezra Stiles, which appeared in the January, 1787, issue of *The American Museum* and reads as follows

Portsmouth, (N H) April 30, 1787

Sir,

In the year 1785, that justly celebrated botanist, Dr William Withering, physician to the general hospital in Birmingham, Great Britain, published a treatise on the *Digitalis Purpurea*, (Fox-glove) and its medical uses, with practical remarks on dropsies and other diseases. This valuable treatise came into my hands the same year, it contains more than a hundred and fifty cases of dropsies, many of them of the worse and most complicated kind, cured or relieved by this efficacious plant. I last year received from London, a small quantity of the dried leaves, and some of the same in powder. From repeated trials here, I am fully persuaded, that neither Dr Withering, nor his numerous correspondents, have exaggerated its salutary effects, it is, perhaps, the most powerful diuretic in nature, and possesses a remarkable quality of abating the acceleration of the heart, and retarding the circulation of the blood

By the last ship from London, and last post from Boston, I was honoured with a very polite, obliging, and interesting letter from Dr Withering, and favoured also with a quantity of seeds of the Fox-glove by him. He writes, "I send more that you will distribute them into other states"

It is with much pleasure that I comply with the doctor's humane wish, in enclosing you a small quantity of them, being fully persuaded you will find equal satisfaction in the cultivation of so useful and ornamental a vegetable, it bears a beautiful purple bell-flower, worthy a place in any garden

I take liberty of transcribing two other passages in the doctor's letter, which, I think, may, with propriety, accompany the seed. "I am more and more convinced, that the *Digitalis*, under a judicious management, is one of the mildest and fastest medicines we have, and one of the most efficacious. I believe it is not necessary to create a nausea or any other disturbance in the system. I never use more than 1 scruple *fol suc* $\frac{1}{2}$ lb of infusion, and in substance rarely more than 3 grains in twenty-four hours"

"*Digitalis* has cured two other cases of insanity in this neighborhood, and three cases of *hemoptoe*, the latter were of a kind attended with a quick bounding pulse, and I directed the medicine, from the quality I knew it possesses of abating the actions of the heart"

I would just mention, that it is a biennial plant, and I conclude it will take some little care to preserve the roots from the severity of the frosts in this cold climate, though it flourishes spontaneously in the fields of England

My good intention must be my apology in the liberty I have taken in troubling a gentleman of your character with so lengthy a letter, altogether professional. I wish to promulgate so valuable an acquisition in medicine, and am so unfortunate as not to be acquainted with any gentlemen of the faculty in your state.

I am, Sir, etc

HALL JACKSON

The Rev Ezra Stiles, president of Yale College

DOUGLAS CARROLL, M.D.

Johns Hopkins Hospital
Baltimore 5

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Essentials of Clinical Allergy By Samuel J. Taub, M.D., professor of medicine, Cook County Graduate School of Medicine, and attending physician in medicine, Cook County Hospital. 8°, cloth, 198 pp., with 16 plates, 2 figures and tables. Baltimore: The Williams and Wilkins Company, 1945. \$3.00.

This manual is written for the general practitioner and medical student. The author has attempted to present a practical clinical approach to the various allergic diseases, as seen in practice. Theoretical discussions have been avoided, and the importance of a broad knowledge of internal medicine is emphasized for the better understanding of allergic conditions. Considerable space is devoted to the discussion of seasonal and perennial hay fever and asthma and to skin disturbances due to allergy. Valuable tables of the pollen flora and pollination dates and skin tests are included in the text. The illustrations of pollen and pollen plants should prove valuable. The final chapter describes various special diets and recipes. This manual should prove of value to the practicing physician.

A Handbook for Dissectors By J. C. Boileau Grant, F.R.C.S., Ed., M.B., Ch.B., professor of anatomy, University of Toronto, and H. A. Cates, associate professor of anatomy, University of Toronto. Second edition. 12°, cloth, 390 pp. Baltimore: The Williams and Wilkins Company, 1945. \$2.50.

The first edition of this manual was written for use in conjunction with *A Method of Anatomy* by the same author. In this edition the handbook has been separated from the latter, all the references to the larger work have been deleted, and instruction for the dissection of every region has been included. The account of the brain is written to meet the needs of the beginner, for whom it should be sufficient. The handbook is designed as an inexpensive guide that students can use without much concern for its ultimate condition but that contains enough information for the identification of any structure met with in the dissection room. It should prove valuable for this purpose.

NOTICES

ANNOUNCEMENTS

Dr. Harry Blotner announces the removal of his office from 189 Bay State Road to 419 Commonwealth Avenue, Boston.

Dr. Joseph Lentune announces the removal of his office from 520 Commonwealth Avenue to 395 Commonwealth Avenue, Boston.

GREATER BOSTON MEDICAL SOCIETY

A meeting of the Greater Boston Medical Society will be held in the auditorium of the Beth Israel Hospital on Tuesday, December 3, at 8:15 p.m. Dr. Shields Warren will speak on the subject "Medical Aspects of the Bikini Experiments." This will be followed by a discussion from the floor.

NEW ENGLAND DERMATOLOGICAL SOCIETY

The regular meeting of the New England Dermatological Society will be held in the Skin Out-Patient Department of the Boston City Hospital on Wednesday, December 4, 2:00 p.m.

JOSEPH H. PRATT
DIAGNOSTIC HOSPITAL

Bennet Street, Boston
Lecture Hall, 9-10 a.m.

MEDICAL CONFERENCE PROGRAM

Wednesday, December 4 — Infections Due to *Bacillus Pyocyaneus* (*P. aeruginosa*) Treatment with Streptomycin. Dr. Malcolm Stanley.

Friday, December 6 — The Present Status of the Peptic Ulcer. Dr. Sara M. Jordan.

Wednesday, December 11 — Xanthomatous Biliary Cirrhosis. Drs. S. J. Thannhauser and H. E. MacMahon.

Friday, December 13 — The Plastic Repair of Burn Wounds. Dr. Malvin F. White.

Wednesday, December 18 — Pediatric Clinicopathological Conference. Drs. James M. Baty and H. E. MacMahon.

Friday, December 20 — Roentgenology in the Study of Heart Disease. Dr. Merrill Sosman.

On Tuesday and Thursday mornings, Dr. S. J. Thannhauser will give medical clinics on hospital cases. On Saturday mornings, clinics will be given by Dr. William Dameshek. Medical rounds are conducted each weekday by members of the staff from 12:00 to 1:00 in the Lecture Hall.

All exercises are open to the medical profession.

Conferences will be discontinued December 24, 1946 through January 11, 1947.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, DECEMBER 5

FRIDAY, DECEMBER 6

*9:00-10:00 a.m. The Present Status of the Peptic Ulcer. Dr. Sara M. Jordan. Joseph H. Pratt Diagnostic Hospital.

*10:00 a.m.-12:00 m. Medical Staff Rounds. Peter Bent Brigham Hospital.

MONDAY, DECEMBER 9

*12:15-1:15 p.m. Clinicopathological Conference. Peter Bent Brigham Hospital.

TUESDAY, DECEMBER 10

*12:15-1:15 p.m. Clinicoroentgenological Conference. Peter Bent Brigham Hospital.

*8:00 p.m. Harvard Medical Society Amphitheater, Peter Bent Brigham Hospital.

WEDNESDAY, DECEMBER 11

*9:00-10:00 a.m. Xanthomatous Biliary Cirrhosis. Drs. S. J. Thannhauser and H. E. MacMahon. Joseph H. Pratt Diagnostic Hospital.

*11:00 a.m.-12:00 m. Medical Clinic Amphitheater, Children's Hospital.

*12:00 m. Clinicopathological Conference (Children's Hospital) Amphitheater, Peter Bent Brigham Hospital.

*2:00-3:00 p.m. Combined Clinic by the Medical, Surgical and Orthopedic Services Amphitheater, Children's Hospital.

*7:15 p.m. Graduate Seminar in Pediatrics. Children's Medical Service, Amphitheater 3A, Massachusetts General Hospital.

*Open to the medical profession.

PRESENT TRENDS IN OBSTETRICS*

S A COSGROVE, M.D.†

JERSEY CITY, NEW JERSEY

THE obstetrician finds his efforts in behalf of pregnant and parturient women consisting of the prevention and alleviation of four great menaces. These are pain, hemorrhage, toxemia and sepsis. The significant trends in practice, therefore, are perhaps best dealt with as pertaining to these subjects.

PAIN

Until a comparatively recent epoch in medical history, pain was considered the inevitable and inescapable lot of child-bearing women. For the past hundred years, however, the search for a method of alleviating the pain of labor has been continuous and assiduous, men have long hoped for the means of making labor completely painless. From time to time it has mistakenly been believed that this ideal objective had actually been accomplished. The procedures devised periodically in this high hope have successively been found to involve such dangers, either for the mother or the baby, as to render their applicability seriously limited. For practical purposes, the means of relieving pain may be divided into two groups.

Analgesic Agents

The first group embraces drugs that make more tolerable the pains of the tedious first stage of labor and a portion of the second stage. They comprise agents truly analgesic in their potentiality, such as morphine, and those that are merely amnesic, obliterating the patient's subsequent recollection of suffering. Agents of these two groups are frequently combined. The number of such agents is large. The most venerable in length of use are opium and its derivatives, such as morphine and heroin. One of the most recent is Demerol, a synthetic preparation quite like morphine in some of its important pharmacologic characteristics.

The danger that principally limits the use of such agents is the marked tendency of all of them to narcotize the fetus and to make for delay and sometimes failure in the establishment of normal respira-

tion after birth. In these respects Demerol, which has had a fairly extensive but perhaps not thoroughly adequate clinical trial in many hands, appears to be the least dangerous.

Another group of drugs having a powerful soporific action combined with a modicum of analgesic and amnesic properties comprises the barbiturates, of which many varieties have appeared. These preparations vary in the promptness, power and duration of their action. For this reason, some attempt has been made to individualize patients in the selection of the particular barbiturate deemed best suited for the situations under which it is administered.

Evidence is accumulating that the most popular agents used a few years ago for the relief of first-stage pain — the so-called "basal analgesics," are far from innocuous, particularly in their effect on the fetus. Increasing recognition of this fact is tending to make them somewhat less popular, but their use is still extensive, and in my opinion they have a distinct place in the resource of the obstetrician.

The only drug whose usefulness depends directly and wholly on its amnesic powers is scopolamine, although several of the others mentioned above have this property in some degree. A few practitioners, appreciating the dangers of the opiates and apparently convinced that the subsequent effect on the parturient patient's psyche in her recollection of an exceedingly painful experience is the most important factor to overcome, have depended largely or solely on the administration of scopolamine for this purpose. The majority of practitioners, however, prefer actually to abolish pain so far as it can safely be done. These men therefore use scopolamine, if at all, only as an adjuvant to other more definitely pain-relieving drugs. Scopolamine is often thus combined with many of the agents already named. It must not be forgotten that scopolamine is derived from one of a dangerously poisonous group of plants. Occasional idiosyncrasy or carelessness in dosage may result in disaster.

Anesthetic Agents

The second group of pain-relieving agents is applied in the management of the terminal phase of

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 13, 1946.
†Clinical professor of obstetrics, Columbia University College of Physicians and Surgeons; assistant medical director, Hudson County and Jersey City hospitals; medical director and superintendent, Margaret Hague Maternity Hospital.

the second stage of labor, characterized by the actual extrusion of the fetus through the vaginal introitus. They are used for more complete and definitive anesthesia against the excruciating pain characterizing this part of labor.

Again the variety of these agents is large. They fall into two distinct and different groups.

The first includes those that act on the brain itself, abolishing pain by narcotizing the entire cerebral sensorium. They are most frequently administered by inhalation, entering the blood stream through the lungs and exerting their physiologic effect on the brain through the blood.

Ever since Simpson, almost a century ago, taking his cue from the first historic surgical use of sulfuric ether, in this very city, applied this agent and subsequently chloroform to the relief of pain in parturition, each one of the many agents devised for inhalation anesthesia for any purpose has been applied to obstetric practice.

Ether, oldest of them all, still retains an important place in the obstetric armamentarium, especially in practice outside hospitals and even in hospitals where the service of expert anesthetists in the administration of other agents is not available. Ether has also been extensively used in the past, and continues to be somewhat used as a labor analgesic, as well as a terminal labor anesthetic, administered in oil by rectum by the well known but now somewhat archaic Gwathmey technic.

Chloroform, used soon after ether and preferred by Simpson, shortly became much the most important obstetric anesthetic and served several generations of physicians well. For the last quarter century it has lost this pre-eminence. It has been accused of a high mortality rate for mothers and of dangerous toxic side-effects, particularly in the liver. It has almost completely dropped out of use in most leading American clinics. I am not sure, however, that it justly deserves the total oblivion into which it has fallen. I suspect that it continues to serve well many physicians practicing outside hospitals, who appreciate its flexibility and would not willingly forego the help that it constantly affords. I am old enough to remember well my own debt to chloroform for service rendered in the past.

Perhaps foremost in hospital use today for the termination of labor by inhalation anesthesia is nitrous oxide, administered with appropriate proportions of oxygen, in an apparatus specially designed for this use. It is reasonably safe. It must be emphasized, however, that its safety is only relative and that it may be exceedingly dangerous in untrained hands. Cyclopropane, ethylene and vinyl ether are to some extent employed.

All these agents, acting centrally on the maternal brain, have the tremendous disadvantage that they also act centrally on the fetal brain. One cannot narcotize the mother by means of them without a

fairly corresponding degree of narcotization of the fetus. Therein lies a serious restriction of their usefulness. Moreover, I have been impressed by the heightened danger represented by the use of the narcotic agents in the fact of their synergism with other agents, particularly opium derivatives, that are frequently included in the regime of balanced analgesia prior to the administration of the inhalation narcotic. Such synergism represents a real jeopardy to the fetus from damaging or fatal asphyxiation.

The other group of agents available for the termination of the second stage of labor, as well as participating to a certain extent in the program of the earlier stages, are applied only to the peripheral neuron of the mother's nervous system. They do not enter the blood stream. They do not affect the general sensorium of the mother, or the cerebral and vital centers. In their entire innocuousness so far as the fetus is concerned, they present tremendous advantages over agents that depend on narcotization of the whole nervous system of the mother. The most widely used agent of this group is novocain. Metycaine, pontocaine and other agents have been similarly employed. Novocain, by its relatively low toxicity, remains probably the standard for this type of anesthesia. These agents are administered by so-called "conduction anesthesia," in which the drug is brought into contact with the peripheral nerves at some point distal to their exit from the spinal cord.

The most immediate and complete of such methods is spinal or intrathecal anesthesia, in which a solution of the anesthetic agent is injected into the thecal sac surrounding the spinal cord at points below the termination of the cord itself, anesthetizing the nerve roots springing from the cord a short distance away from their origin. Another is caudal anesthesia, in which solutions of the anesthetic agent are injected into the spinal canal external to the thecal sac, through the hiatus of the sacrum, exerting their anesthetic effect on the nerve roots as they traverse that space or immediately beyond it where the neurolemma ends. Thirdly, the anesthetic agent may be so injected as to bathe specific principal nerve trunks in continuity, as in parasacral injection. Finally, local infiltration, frequently combined with conduction anesthesia of a few important nerve trunks, may be employed.

These methods of anesthesia, applied to the peripheral nerve segment, are taking an increasing place in obstetric practice. This is regarded as a constructive tendency because of the vast advantage to the fetus embodied in these methods as compared to those that specifically poison the brain through the blood stream.

These procedures also have many points of advantage so far as the welfare of the mother is concerned, particularly when the mother is handicapped by certain intercurrent diseases either more or less

specific for pregnancy or not depending directly on the fact of pregnancy. Each has its own advantages and disadvantages.

I have employed spinal anesthesia in obstetrics for twenty years. There has been and continues to be much criticism of its obstetric use from the standpoint of danger of sudden death. From an experience of many thousands of cases, however, I believe that it constitutes an ideal method for vaginal delivery, in which it can be used in small enough dosage to eliminate this danger and in which I have observed no other important unpleasant sequelae. I have also used spinal anesthesia extensively for obstetric laparotomies, with a low mortality. In consideration of the handicaps presented by the patients who have succumbed, however, I am not impressed with the probability that any other method of anesthesia in those particular cases would have been significantly less dangerous.

My experience has been with the so-called "one-shot" or single-injection method. Continuous spinal anesthesia, in which successive small doses are administered through a needle left in situ, has recently had increasing use. In spite of the bitter and, in my opinion, at times strongly biased and unjust criticism of spinal anesthesia, there is no doubt that it is being more and more widely used.

Caudal anesthesia, a method by no means new, was brought sharply to the attention of the obstetric world about five years ago by Hingson, an honest and well qualified anesthetist in the United States Public Health Service, in the form of continuous caudal anesthesia. The first reports were undoubtedly overenthusiastic. Hingson apparently thought that he had actually achieved in this method an almost universally applicable approach to the obstetrician's dream of painless labor. This belief was shortly disappointed. With increasing experience, he recognized and defined a number of limitations and dangers that reduced the method to one not applicable in the vast majority of cases from the initiation of labor pains or for an unlimited time after the inauguration of the anesthesia. From time to time he has honestly re-evaluated the indications and contraindications, as well as the advantages and disadvantages, of the method.

At the present time it seems that caudal anesthesia is not, in any but the most expert hands, properly applicable in more than one out of four or five patients or for a total period longer than six to eight hours. Distinct dangers inhere in the method, avoidable only by the most meticulously expert technic. This fact makes it essential that the procedure be used only by physicians and nurses especially trained in this technic. It requires in each case the constant close attention during the whole period of anesthesia of either the responsible obstetrician or another physician, such as an especially trained anesthetist. This necessarily limits the number of patients who can derive the benefit

of this method. It is obvious that, except in large teaching hospitals where caudal anesthesia can be afforded to patients only on the basis of its educational value, the necessarily high cost entailed by the close attention of highly qualified physicians is beyond the capacity of the majority of patients.

The most obvious dangers of caudal anesthesia are the inadvertent injection of the anesthetic solution into the thecal sac, the injection of the solution directly into the blood stream and, of course, the rare but ever present danger of infection of the meninges. Other technical dangers are recognized. The anesthesia is neither so prompt nor so uniform as spinal anesthesia, the dangers are of the same nature and the difficulty and the cost are greater.

Results in successful cases are most satisfactory, and many a woman has been deservedly grateful for the relief of suffering afforded. The procedure is not, however, and can never be the universal panacea that it was originally hoped to be. It is a resource that the well qualified obstetrician should consider at his command, but it is incapable of supplanting other methods in the majority of cases.

Infiltration anesthesia, with or without peripheral nerve block, is the safest of all anesthetic methods. Some of its proponents claim that there has never been a fatality justifiably attributable to it. This is probably such an exaggeration as the use of the word "never" almost always implies in medicine. The procedure is not universally applicable, since neurotic patients are not favorable subjects, and unbiased observers are not infrequently impressed with its lack of complete efficiency. A modicum of special training and adept technic and sometimes a high degree of patience and tolerance on the part of both the operator and the patient are required. There is undoubtedly, however, a steadily increasing use of this method, and since the possibility of death or serious accident is almost completely negligible, this trend is indeed salutary.

HEMORRHAGE

The reduction of the danger of hemorrhage, which is actually the most frequent of the purely obstetric causes of puerperal death, continues along lines long since laid down. They include the following: better training in exact and early recognition of ectopic gestation, placenta previa and abruption of the placenta, less reliance on the outmoded packing of the uterus, a more intelligent search for the sources of bleeding in the various parts of the parturient canal and uterus, and the application of more definitive operative therapy to several of these sources when demonstrated, increasing knowledge and appreciation of the significance of Rh-factor incompatibility, not only concerning the health and survival of the fetus, but also regarding the dangers of an unfavorable transfusion reaction in the mother, and the inclusion of blood-group and Rh-

the second stage of labor, characterized by the actual extrusion of the fetus through the vaginal introitus. They are used for more complete and definitive anesthesia against the excruciating pain characterizing this part of labor.

Again the variety of these agents is large. They fall into two distinct and different groups.

The first includes those that act on the brain itself, abolishing pain by narcotizing the entire cerebral sensorium. They are most frequently administered by inhalation, entering the blood stream through the lungs and exerting their physiologic effect on the brain through the blood.

Ever since Simpson, almost a century ago, taking his cue from the first historic surgical use of sulfuric ether, in this very city, applied this agent and subsequently chloroform to the relief of pain in parturition, each one of the many agents devised for inhalation anesthesia for any purpose has been applied to obstetric practice.

Ether, oldest of them all, still retains an important place in the obstetric armamentarium, especially in practice outside hospitals and even in hospitals where the service of expert anesthetists in the administration of other agents is not available. Ether has also been extensively used in the past, and continues to be somewhat used as a labor analgesic, as well as a terminal labor anesthetic, administered in oil by rectum by the well known but now somewhat archaic Gwathmey technic.

Chloroform, used soon after ether and preferred by Simpson, shortly became much the most important obstetric anesthetic and served several generations of physicians well. For the last quarter century it has lost this pre-eminence. It has been accused of a high mortality rate for mothers and of dangerous toxic side-effects, particularly in the liver. It has almost completely dropped out of use in most leading American clinics. I am not sure, however, that it justly deserves the total oblivion into which it has fallen. I suspect that it continues to serve well many physicians practicing outside hospitals, who appreciate its flexibility and would not willingly forego the help that it constantly affords. I am old enough to remember well my own debt to chloroform for service rendered in the past.

Perhaps foremost in hospital use today for the termination of labor by inhalation anesthesia is nitrous oxide, administered with appropriate proportions of oxygen, in an apparatus specially designed for this use. It is reasonably safe. It must be emphasized, however, that its safety is only relative and that it may be exceedingly dangerous in untrained hands. Cyclopropane, ethylene and vinyl ether are to some extent employed.

All these agents, acting centrally on the maternal brain, have the tremendous disadvantage that they also act centrally on the fetal brain. One cannot narcotize the mother by means of them without a

fairly corresponding degree of narcotization of fetus. Therein lies a serious restriction of their usefulness. Moreover, I have been impressed by heightened danger represented by the use of the narcotic agents in the fact of their synergism with other agents, particularly opium derivatives, that are frequently included in the regime of buprenorphine analgesia prior to the administration of the inhalation narcotic. Such synergism represents a real jeopardy to the fetus from damaging or fatal asphyxiation.

The other group of agents available for the termination of the second stage of labor, as well as participating to a certain extent in the program of the earlier stages, are applied only to the peripheral neuron of the mother's nervous system. They do not enter the blood stream. They do not affect the general sensorium of the mother, or the cerebral and vital centers. In their entire innocuousness as far as the fetus is concerned, they present tremendous advantages over agents that depend on narcotization of the whole nervous system of the mother. The most widely used agent of this group is novocain. Metycaine, pontocaine and other agents have been similarly employed. Novocain, by its relatively low toxicity, remains probably the standard for this type of anesthesia. These agents are administered by so-called "conduction anesthesia," in which the drug is brought into contact with the peripheral nerves at some point distal to their exit from the spinal cord.

The most immediate and complete of such methods is spinal or intrathecal anesthesia, in which a solution of the anesthetic agent is injected into the thecal sac surrounding the spinal cord at points below the termination of the cord itself, anesthetizing the nerve roots springing from the cord a short distance away from their origin. Another is caudal anesthesia, in which solutions of the anesthetic agent are injected into the spinal canal external to the thecal sac, through the hiatus of the sacrum, exerting their anesthetic effect on the nerve roots as they traverse that space or immediately beyond it where the neurolemma ends. Thirdly, the anesthetic agent may be so injected as to bathe the specific principal nerve trunks in continuity, as in parasacral injection. Finally, local infiltration, frequently combined with conduction anesthesia of a few important nerve trunks may be employed.

These methods of anesthesia, applied to the peripheral nerve segment, are taking an increasing place in obstetric practice. This is regarded as a constructive tendency because of the vast advantage to the fetus embodied in these methods as compared to those that specifically poison the brain through the blood stream.

These procedures also have many points of advantage so far as the welfare of the mother is concerned, particularly when the mother is handicapped by certain intercurrent diseases either more or less

prompt and adequate treatment and timely termination of pregnancy in toxemia applies with special emphasis in the hypertensive patient with superimposed toxemia

SEPSIS

The availability of the sulfonamides and of several antibiotic agents of high efficiency has greatly increased the resources of the obstetrician in treating the septic complications of pregnancy, labor and puerperium

Streptomycin, not yet generally available, appears to promise great value in certain infections not amenable to other antibiotics. It is to be hoped that it may presently be released on a commercial scale and that similar agents may be forthcoming

It must be cautioned, however, that these valuable agents are not universally efficacious, even when culture studies appear to indicate them specifically. They must not be depended on to replace, or justify carelessness in, the surgical technics necessary and efficacious in preventing sepsis. The use of these agents in a prophylactic sense, or on a tentative basis lacking knowledge of specific bacteriologic indications, is debatable, but the uncertainty of bacteriologic findings and the loss of time in determining them appear to justify such practice.

The increasing recognition of the value of rather small, frequently repeated blood transfusions in the treatment of infective complications is wholly constructive. This method is occasionally limited by unfavorable reactions, however. Especially meticulous care is necessary in grouping and cross-matching

The present interest, amounting perhaps to a craze, in the surgical treatment of thrombophlebitis and phlebothrombosis on the part of many surgeons is believed to have little support from the obstetrician. The rarity of puerperal death from embolism, the efficacy of other methods of treatment and the sometimes long-lasting serious sequelae of surgery seem to justify this attitude

* * *

Finally, it is believed that there is a continuing and increasing trend toward what Dr Willard Cooke, of the University of Texas, calls "rationalism" in obstetrics. This is considered a better term than "conservatism" or "radicalism," which are hard to define and often interchangeable. Perhaps the wish is father to the thought that this trend is wholly desirable. Rationalism includes such objectives as Bingham's fine phrase, "Keep the normal obstetric case normal," and the principle that medical and surgical complications of pregnancy should be appropriately medically and surgically treated, without interference with pregnancy. It does not embrace, on the one hand, blind confidence that pregnancy always is and will remain physiologic, or on the other, a baseless fear that pregnancy may not be successfully managed in the presence of almost any complication. Intelligent improvement in obstetric practice will be principally predicated on thoughtful individualization of cases on the basis of such rationalism

55 Clifton Place

factor determination as a routine part of early prenatal care.

A further vital step in combating hemorrhage is increasing provision and improvement in the operation of blood and plasma banks. A recent temporary augmentation of the resources of hospitals in this respect has been the release to them, through state agencies, of large amounts of dried plasma originally provided for the armed forces. Frequent difficulty in obtaining compatible blood from the standpoint of both blood-grouping and Rh-factor compatibility is being lessened by technical improvements in the preparation and storing of blood.

The work of Dr. Diamond, of Boston, in such improvement is significant. The artificial neutralization of the A and B agglutinins permits the pooling of blood compatible for all recipients so far as the basic blood groups are concerned. Such pooled blood may then be divided into two pools, depending on its Rh-factor characteristics. Selection of bloods for individual recipients then depends only on the Rh characteristics of the recipients.

It is entirely possible that the more widespread determination of the titer of Rh antigens in Rh-recipients may further simplify this problem. The whole effect of these technical improvements, of course, is to save time in the administration of blood under circumstances in which time is a highly important consideration.

The blind unreasoning dependence on the antepartum administration of vitamin K that apparently possessed so many members of the profession only recently is being replaced, on the basis of objective studies of its results, by a saner realization of the limitations of this therapy. Thus, the naïve statement heard not too long ago in one of the leading special societies, "We shall not worry about post-partum hemorrhage in the mother, for, of course, she has received vitamin K before labor," is now recognized for its manifest absurdity. Even the efficacy of this agent in reducing infant mortality, either from hemorrhagic disease of the newborn or from bleeding on a traumatic basis, is open to serious question.

These facts do not negate the present probable wisdom of using vitamin K in post-partum uterine inertia or in infants suspected of suffering from actual or potential hemorrhage. But it is only a possibly useful drug, not a miraculous substitute for other time-tried methods.

TOXEMIA

It cannot be said that there has been any significant advance in the knowledge of the pathogenesis of toxemia, in more satisfactory classification or in methods of treatment whose objectives are fairly well standardized in spite of a wide variety of detail in the methods themselves. Nor is there any true prophylaxis for toxemia except that embodied in early institution and intensive

performance of prenatal supervision. Meticulous attention to all the details of hygiene, proper diet and vitamin balance should be embodied in the program.

Clearer concepts of the necessary treatment of the toxemias, however, are emerging. The objectives of such treatment are conservation of maternal life from immediate hazard, conservation of fetal life and conservation of maternal health and long-range survival. The primary requisites to accomplish the objectives in the highest degree are early recognition of toxemia by presumptive and slight clinical evidence, prompt institution of the fullest regimen for control of the disease when discovered and definite—if necessary, radical—control of the time the disease is permitted to persist.

There is no degree of toxemia that is clinically negligible. Even occult edema suggested by any exorbitant weight gain should be considered, and treatment at once begun. More definite indications, even in only slight degree, require the fullest program of treatment, generally including hospitalization. Fulmination of severe toxemia is not always presaged by orderly progression from mild through recognizably severer forms. In a high percentage of cases eclampsia supervenes directly on pre-eclampsia of the supposedly mild type.

The only definitive treatment of any form of toxemia is termination of pregnancy. As already pointed out, all the objectives of treatment depend for success on limiting the time that the toxemia is allowed to persist. Time of interrupting the pregnancy is therefore of utmost importance. This time necessity often warrants radical means in preference to less certain and protracted methods. Cesarean section is sometimes appropriate on this basis alone. Such termination of pregnancy is surely salutary in reducing immediate maternal risk and has unmistakably been shown to be equally valuable so far as the mother's subsequent health and life expectancy are concerned. It is not inimical (at least after the thirty-fourth week) to the baby's chances of survival—the single hazard of prematurity is merely substituted for the many dangers from abortion, suboxidation, malnutrition and perhaps direct toxicity.

The single form of toxemia in which the foregoing considerations are not true is eclampsia, in which the seriousness of the clinical picture necessitates entire concentration on the medical treatment of the mother. The baby's interest must be subordinated to hers. Abundant evidence proves that only rarely and under certain special conditions is the eclamptic mother's interest served by deliberate interruption of pregnancy.

Pre-existing hypertension represents only a moderate immediate hazard to the pregnant patient and the fetus, and virtually no remote hazard, provided superadded toxemia does not occur. Hence, all that has been said about the early recognition,

point is the appearance of bile-stained urine, which is frequently observed by the patient before jaundice develops.

The icteric phase averages two to four weeks, and when jaundice appears fever subsides and the gastrointestinal complaints are apt to become prominent. Anorexia, which is peculiarly severe, nausea and less often vomiting, epigastric discomfort and pain in the region of the liver — especially on jarring, bending, rolling on the right side in bed and sometimes on coughing and deep breathing — are frequent and significant complaints. On careful examination the liver is often found to be enlarged and tender, and the spleen may be palpable. Jaundice as a general rule reaches a peak in about a week and begins to fade fairly rapidly. Soon after jaundice appears there is usually a remarkable amelioration of complaints, return of appetite and disappearance of the feeling of malaise. Abdominal discomfort, lassitude and other symptoms may persist, but liver tenderness tends to subside and the liver gradually returns to normal size.

In some cases icterus becomes progressively worse, a marked fetor hepaticus is noted²⁵ and the patient becomes restless, irritable and delirious. Coma, often with hemorrhagic manifestations, develops, and death from acute hepatic necrosis ensues.

The convalescent phase, defined as the period following clearance of the jaundice and cessation of all signs of active disease, usually lasts about seven to fourteen days. Barker and his associates²²⁻²⁴ have clearly pointed out that proper evaluation of recovery, especially regarding toleration of activity, is essential if relapse and chronic hepatitis are to be avoided.

DIAGNOSIS

Except in the presence of an epidemic, preicteric cases and those without icterus are not likely to be recognized in civilian practice. From the diagnostic standpoint, a history of association with jaundiced persons or the administration of blood, plasma, serum and parenteral fluids is of great importance. Clinical findings — especially severe anorexia and nausea, tenderness over the liver and bile-stained urine — are also of particular significance.

In civilian as in military life, jaundice in young people usually offers few diagnostic problems. Sporadic cases of infective hepatitis in civilian life, however, may present serious diagnostic difficulties. White,²⁷⁻²⁹ discussing diagnostic problems in the presence of jaundice, emphasizes the fact that infective hepatitis can occur at any age, in his series of 500 cases of jaundice, there were 101 patients with acute infective hepatitis, 60 per cent of whom were over thirty years of age. In an older and more heterogeneous group, greater possibilities exist for the occurrence of obstructive

jaundice due to biliary-tract disease and cancer. In addition, the various toxic, chemical and nutritional factors causing hepatitis and cirrhosis are more frequently encountered.

In an analysis of a personal series of 206 cases of jaundice in civilian practice, there were 82 cases of obstructive jaundice due to biliary-tract disease and cancer, and various forms of hepatitis and cirrhosis accounted for 124 cases, 42 of which were infective hepatitis. In 6 patients jaundice followed the administration of blood and plasma, 4 patients had associated with other jaundiced persons, and 32 cases were sporadic. In the 32 sporadic cases, 20 patients were over thirty-five years of age, and all but 1 of the severe cases and the 3 fatal cases occurred in patients over forty years of age. This agrees with the rather general impression that older patients do not stand liver damage so well as younger people, and Jones²⁹ points this out in association with chemical liver intoxication.

The most serious and practical problem in the treatment of the jaundiced patient is to decide whether the case is a medical or a surgical one.^{27, 28, 30} On the one hand, surgical intervention may save a life, whereas on the other, ill advised exploration may precipitate liver failure and death. The differential diagnosis between hepatitis and extrahepatic obstruction due to common-duct stone or cancer rests fundamentally on a careful evaluation of the history and clinical aspects of the case. Of special diagnostic value are such factors as the mode of onset, the degree, duration and course of the jaundice, the presence, character and location of pain, the occurrence of anorexia and nausea, the size, character and tenderness of the liver and the presence of an enlarged and nontender gall bladder or a palpable spleen. It has become increasingly evident that jaundice due to obstruction is not a surgical emergency and that proper preparation of the patient and evaluation of liver function have greatly reduced the mortality of operative procedures on the biliary tree. This increased period of observation, which has also allowed time for further study, constitutes in itself an important factor in limiting diagnostic errors.

Clinically and from the laboratory standpoint, acute infective hepatitis and that due to various chemicals, drugs and bacterial toxins closely resemble each other.³¹ Differentiation is usually difficult and in some cases impossible unless there is evidence of exposure to the hepatotoxic factor. Fortunately, chemical injury to the liver is infrequent as a general clinical problem, and the same principles of management can be applied to almost all forms of hepatocellular damage.

A great deal has been written concerning the role of laboratory tests in diseases of the liver and the extrahepatic biliary tracts.³²⁻³⁵ Although in themselves not diagnostic, a group of relatively simple procedures, carried out repeatedly, contribute in-

THE DIAGNOSIS AND TREATMENT OF INFECTIVE HEPATITIS*

WILLIAM C. MOLONEY, M.D.†

BOSTON

INFECTIVE hepatitis has been known chiefly as a disease of war, but it has been described frequently during the past three decades as a sporadic, endemic and epidemic disease occurring in civilian populations all over the world.¹⁻⁴ During World War II an unprecedented pandemic of infective hepatitis occurred, and the increasing prevalence of this serious disorder in civilian practice makes it imperative to utilize the newer concepts of the disease and to apply the knowledge and experience gained during the recent conflict to the best diagnostic and therapeutic advantage.

It is impossible, in the present state of knowledge, to designate the disease by an accurate nomenclature, in this paper infective hepatitis is used as a general term to include the sporadic and epidemic form (infectious hepatitis) and the parenterally transmitted disorder (homologous serum hepatitis). In view of the modern concept of the pathology of the disease, the term "catarrhal jaundice" should be discarded, not only because it is well established that many cases of infective hepatitis occur without jaundice but also because catarrhal jaundice has become synonymous with a benign and self-limited process, whereas there is increasing evidence that infective hepatitis is a serious and often treacherous disease.⁵⁻⁷

GENERAL CONSIDERATIONS

In spite of the vast amount of material available and the intensive studies carried out in this country and abroad, knowledge concerning infective hepatitis is still deficient, especially in the etiologic and immunologic aspects of the disease. In recent papers Janeway⁸ and Paul⁹ point out that the etiologic agent of infective hepatitis has never been seen, cultured or transmitted to laboratory animals. Since the agent passes through bacteria-tight filters, it has been considered to be a virus. It is stable, resisting heating to 56°C for at least thirty minutes, and withstands drying, freezing and the ordinary antibacterial preservatives. By means of experimental transfer in men, it has been shown that in the preicteric and early icteric stages of epidemic hepatitis the feces and blood contain the infective agent.^{9, 10} The blood of patients with serum hepatitis, in the incubation period and early icteric phase, has reproduced the disease in human volunteers when given by mouth and parenterally.¹¹⁻¹³ There are also reports on the infectivity

of urine and nasopharyngeal secretions, but the studies await further confirmation.^{9, 14}

Biopsy and autopsy material indicates that the essential pathologic process is a degeneration and necrosis of parenchymatous liver cells, with an inflammatory reaction and cellular infiltration in the portal spaces and sinusoids.^{15, 16} Usually, complete regeneration occurs, but fibrotic changes occur in classic cirrhosis have been described by Dible and others.¹⁷ Fatal cases present the picture of acute or subacute yellow atrophy of the liver.

Most investigators believe that serum hepatitis and epidemic hepatitis cannot be differentiated pathologically or clinically.¹⁸ Paul⁹ and Janeway, however, state that there are important differences such as a lack of cross immunity and the fact that the infective agent is present in the stools of patients with epidemic hepatitis and absent in those of patients with serum hepatitis. Epidemic hepatitis is often spread by contact, serum hepatitis rarely transferred in this fashion. Gamma globulin seems to be protective against the epidemic form but has apparently been ineffective to date in the prevention of serum hepatitis.¹⁹ From recent reports it is also noteworthy that the mortality of serum hepatitis is much higher than that in the epidemic type.^{5, 20, 21}

At present it is not clear whether these forms of hepatitis are caused by the same virus, by different or attenuated strains of the same virus or by different etiologic agents producing a similar clinical entity.

CLINICAL ASPECTS

Excellent and detailed descriptions of the clinical features of infective hepatitis have appeared in the literature.^{22, 23} The disease typically has preicteric, icteric and convalescent stages, although some patients have jaundice as the initial complaint and in others icterus may not develop—the *sine icterus* group.²⁴

The preicteric phase is usually of five to seven days' duration, and there is frequently an acute febrile onset accompanied by a chilly feeling, headache, malaise, weakness, generalized aches and pains, anorexia, nausea and occasionally vomiting. Sporadic cases encountered in civilian practice may have an afebrile and insidious onset, resembling in this respect many cases of serum hepatitis.

Physical signs are few, hepatic tenderness may be present, but enlargement and tenderness of the liver are likelier to occur just before or with the onset of jaundice. A most important diagnostic

†Assistant professor of clinical medicine, Tufts College Medical School; visiting physician, Carney and St. Elizabeth's hospitals.

containing unsaturated fatty acids, have been limited in the diet, but Hoagland⁵³ has recently questioned the wisdom of this practice. Until further clinical and experimental data are available, a diet consisting of 350 to 500 gm. of carbohydrate, 150 gm. of protein and 50 gm. of fat may be considered adequate. Protein may be increased by the addition of supplementary feedings of methionine—substances rich in casein, such as cottage cheese, skimmed milk and various protein concentrates. When necessary, in vomiting or extremely sick patients, parenteral glucose, plasma, whole blood and purified human albumin⁵ may be utilized. Since the effect of the administration of parenteral amino acids on the liver in acute infective hepatitis is still under investigation and since a few untoward reactions have been reported, the use of these products should await further study.⁵⁴

The specific therapeutic indications and the exact dosage of vitamins necessary in acute infective hepatitis are unknown. Recent work indicates that large unbalanced doses of one or more of the components of vitamin B complex may be injurious to the liver.⁵⁵ During the acute stage of the disease a reasonable therapeutic formula, modified after Jolliffe,⁵⁶ seems to be the administration of 30 mg. of thiamine chloride, 10 mg. of riboflavin and 100 mg. of niacin, 300 mg. of vitamin C, 50,000 units of vitamin A and 2000 units of vitamin D.

To date the results of therapy with choline chloride and methionine in acute infective hepatitis have been equivocal,^{56, 57} and until more data are available methionine contained in high-protein diets seems to be an adequate and practical source of this expensive amino acid.⁵¹

SUMMARY

Under the term "infective hepatitis," two acute types are discussed: epidemic (and sporadic) hepatitis, transmitted in all probability by the intestinal-oral route, and serum hepatitis, transferred parenterally. Although these forms of hepatitis are alike pathologically and clinically, certain differences are summarized, since the infective agent has not been actually isolated, it is not clear whether the disorders are caused by the same or different etiologic agents.

The clinical and laboratory features of acute infective hepatitis are discussed, and it is pointed out that, contrary to military experience, cases encountered in civilian life may present serious diagnostic problems.

Prevention of infective hepatitis presents many difficulties, but certain preventive measures are of importance, especially in the parenteral transfer of serum hepatitis.

There is no specific therapy for infective hepatitis, but a program of adequate bed rest and proper diet is effective in the management of the disease.

Acute infective hepatitis is becoming more prevalent in civilian practice. It carries with it a serious morbidity and is probably an antecedent factor in chronic liver damage and cirrhosis more frequently than it is realized. The disease is treacherous and, at times, fatal, especially in old and debilitated patients.

valuable aid in diagnosis and in the evaluation of liver damage

In the preicteric stage and in cases of infective hepatitis without jaundice, the laboratory can be of special assistance. The demonstration of bilirubin⁴⁰ and abnormal amounts of urobilinogen in the urine,³⁷⁻³⁹ positive cephalin-flocculation⁴⁰ and thymol-turbidity⁴¹ tests and the abnormal retention of bromsulfalein (as modified by Barker²²) are the most significant laboratory findings.

In the icteric stage of infective hepatitis the degree and course of jaundice can be followed most accurately by serum bilirubin determinations.⁴² The cephalin-flocculation and thymol-turbidity tests are positive with few exceptions in acute hepatitis but are usually negative in extrahepatic obstructive jaundice unless it is of long standing or associated with ascending disease of the biliary tract. The serial determination of urinary and fecal urobilinogen is one of the most useful laboratory aids in the detection of liver damage and in determining the character of obstruction.³⁸

A number of routine laboratory procedures and other liver-function studies may be utilized in special problems. Sometimes, as Watson⁴³ aptly states, "One might say that it was necessary to take a vote of the various functions of the liver in order to determine its ability to work as a unit." In any event, the proper use and interpretation of laboratory tests in relation to a careful history and physical examination ensures a correct diagnosis in the vast majority of cases.

PREVENTION

Since the infective agent has been demonstrated in the stools of patients with epidemic hepatitis during the preicteric and early icteric phases and possibly in nasopharyngeal secretions and urine, patients should be isolated, and dish, bedpan and urinal precautions employed at least during the acute stage. Water-borne epidemics due to contamination of the water supply have been described in camps, and since ordinary methods of purification of water do not destroy the infective agent, precautions regarding proper camp sanitation should be strictly enforced.⁴⁴

In this era of parenteral therapy, the increasing prevalence of serum hepatitis, which is by all accounts the most pernicious form of the disease, is a serious problem in civilian practice. It is now well recognized that the disease is transmitted by whole blood, plasma and serum, regardless of the manner of preservation. Janeway⁵ and others⁴⁵ have pointed out that greater opportunity for transfer of the infective agent is offered by large pools of plasma obtained from a number of donors than by blood or plasma from a single donor. The difficulty in eliminating potentially infective blood donors is obvious, since the infective agent is present in the blood long before clinical or labora-

tory evidence presents itself.^{5, 12} Nevertheless prospective donors showing any of the clinical laboratory findings of infective hepatitis, as well as those who within a year have had jaundice have been exposed to other jaundiced persons who have themselves had blood, plasma or parenteral therapy, should not be accepted.

British investigators recently demonstrated that serum hepatitis can be transmitted by contaminated syringes.^{46, 47} This imposes the obvious duty on office, clinic and hospital practice of using only properly sterilized syringes for intramuscular, subcutaneous and intravenous work.

The value of gamma globulin in the prevention of epidemic hepatitis has been well established,^{5, 48} and in civilian practice under epidemic conditions gamma globulin could be used. Recent reports indicate, however, that gamma globulin is not protective against serum hepatitis.¹⁹

Oliphant⁵⁰ has stated that ultraviolet radiation destroys the infective agent of serum hepatitis, and Grossman and Saward⁴⁶ suggest that this method be utilized to practical advantage. If feasible, this form of radiation may solve an extremely vexatious problem.

TREATMENT

There is no specific therapy for infective hepatitis but extensive clinical experience during the war has demonstrated the efficacy of intelligent medical care.

It is universally recognized that adequate bed rest is essential. No hard and fast rules are possible, but on the average three to six weeks are required before the active phase of the disease is over. When jaundice has cleared and the liver enlargement and tenderness have subsided, limited activity may be allowed and gradually increased over a period of seven to ten days. As Barker and co-workers^{22, 26} have clearly demonstrated, the real test of recovery from liver damage is tolerance for activity. During convalescence, if there is a return of any signs of activity of hepatitis, manifested especially by tenderness or enlargement of the liver, further bed rest should be required.

Liver-function tests may be employed to good advantage during convalescence. Clearing of bile and abnormal amounts of urobilinogen from the urine, absence of direct reacting serum bilirubin and normal excretion of bromsulfalein furnish the best laboratory evidence of recovery from acute infective hepatitis.²²

In the present state of knowledge it is difficult to evaluate the specific role of various dietary factors in the treatment of acute infective hepatitis. There is general agreement on the beneficial effect on the liver of large amounts of carbohydrate, and the value of a high-protein intake, especially one containing the essential amino acid, methionine, seems well established.^{51, 52} Fats, specifically those

population of diverse dietary habits and with great sectional differences in the types and amounts of foods available. In this country, moreover, we experienced an almost complete immunity to the hazards of war and the experiences of any noticeable hardships due to it, which certainly affected the attitude of our population toward its inconveniences. England's food-rationing program may have been stricter, but ours was undoubtedly more difficult to administer.

The Subcommittee on Medical Food Requirements recognized eleven conditions or groups of conditions that might reasonably require extra rations, and prescribed the upper limits of rationed foods that might reasonably be granted under the conditions existing in 1943. This list consisted of diabetes mellitus, active tuberculosis, chronic nephritis of the nephrotic type, cirrhosis of the liver, severe hepatitis, chronic ulcerative colitis, chronic suppurative diseases, sprue, obstructive gastrointestinal lesions, high intestinal fistulas and severe burns. No medical reason for any extra allotments of sugar was recognized, and it was even recommended that diabetic patients asking for additional rations forfeit their sugar allowance.

Another point emphasized by the committee — and this deserves special attention — was that its recommendations were intended only as a guide and should not be allowed to "vitiolate the scientifically necessary flexibility inherent in any wise system of rationing for the sick." The desirability of medical-appeal committees was also noted.

It is obviously impossible to determine how much rationed food any person may require without knowing first how much and what types of unrationed foods are available. When it is realized that the availability of unrationed foods varied from time to time and from place to place, that certain types of foods went on and off the ration lists, that point values were subject to frequent change and that human beings vary in their needs and capacities in disease as well as in health, it is understood how inaccurate rationing is at best, and how great is the need of flexibility in the system.

Stare,² nevertheless, in a lecture in 1943, showed how easily the average diet could be balanced, based on the traditional 70 gm. of protein a day and on a weekly meat ration of 840 gm., or approximately 1¾ pounds.

The committee of the Massachusetts Medical Society appointed to aid the district rationing officer was one of the first in the field, and from the beginning of its duties until now, when, it is fondly hoped, the duties are nearing their end, it has enjoyed the utmost co-operation from the Regional Office of Price Administration.

With little available precedent to follow when it first assumed its duties, the committee sought advice from various authorities in different branches of medical practice. The standards established for

diabetic patients, by far the most numerous group requesting extra allotments, were accepted as standards for most groups, and seemed to be in general satisfactory. These consisted of 32 pounds of rationed processed foods and 40 pounds of rationed meats and fats in total, including the normal basic allotment, for a two-month period. This allowance, which at that time practically doubled the basic rations, was found to be consistent with the allowances suggested by the Subcommittee on Medical Food Requirements when these recommendations made their appearance.

Local rationing boards were given the privilege of granting up to these maximum amounts on certificates of necessity properly filled out by registered physicians, and all other requests were regarded as those that should properly be reviewed by the medical committee. Since the number of certificates thus honored rose to an alarming degree, however, the Office of Price Administration limited to diabetes and active tuberculosis the conditions for which boards could grant requests, within the quantitative limits established by the medical committee.

A *cause célèbre* was furnished late in 1943 by the application of a defense plant for extra meat allowances for several hundred of its employees. The certificates presented for each of these men, who worked long hours at the open forge and in the heat treatment of metal, was for 3 pounds of rationed meat a day, on the basis of undue fatigue and extreme loss of weight. At that time the basic *weekly* ration was approximately 1½ pounds of meat, fats and oils. It is, of course, absurd to maintain that a diet adequate for a stenographer should also be adequate for a steel worker. Such a policy may be democratic, but it is not equitable. It seemed to the medical committee, however, equally absurd that the steel worker should require over fourteen times as much rationed meat as his fellow patriots.

This problem was studied by the Harvard Fatigue Laboratory, the State Department of Labor and Industry and the War Food Administration, which found that no supplemental ration need be supplied because of a consumer's occupation. Subsequently, the Office of Price Administration made provision for workers in industry by permitting employers to set up in-plant feeding operations where more generous per-capita allowances were made than obtained in commercial restaurants.

The scope of the advisory committee's functions increased, perhaps because of its own lack of sophistication in failing to escape added responsibility. Having been appointed in May to aid the district rationing officer, it found in October that the district had been enlarged to include all the Commonwealth, shortly thereafter, the district office was merged with the regional office, and a committee appointed by the president of the Massachusetts Medical Society soon found itself, vicariously, also

SOME OBSERVATIONS ON THE RECENT FOOD-RATIONING PROGRAM*

JOSEPH GARLAND, M.D.†

BOSTON

ON March 1, 1943, this country entered a revolutionary period in its history, for on that day it embarked on a food-rationing program that was to last two and three-quarter years, and on which the final word has not yet been spoken. Then, as the *Journal of the American Medical Association* phrased it, "the public's traditional peacetime latitude of dietary choice, limited only by ability to pay, was abruptly curtailed," and the Office of Price Administration became the official agency to administer the new program of point rationing.

Sugar, a luxury article of diet, had already been rationed for nearly a year, at the present time, nine months after V-J Day, sugar is the only rationed food, although the balance between supply and demand of other foods is still far from satisfactory, even in this food-producing country, and countless millions of the world's inhabitants face the worst famine in history.

Almost immediately, when rationing went into effect, the problem was encountered of consumers who were unable, or who considered themselves unable, to subsist on the allotted rations and claimed special consideration because of "medical necessity." Extra allowances for those who required them on the grounds of sickness were accordingly granted on a physician's certification of necessity, but the subsequent avalanche of requests showed the need for some method of controlling this dietetic enthusiasm. It became apparent that medical panels would be needed to sift the applications, to advise

the administrative authorities on the apparent justice of the various claims and to aid the medical profession in its own task of selecting patients and physical conditions that might require a tempering of the rules necessitated by the national emergency.

Logically, the state director of the Office of Price Administration sought the help of the president of the Massachusetts Medical Society, who appointed a committee to aid the district rationing officer in May, 1943. On the national level the Office of Price Administration called on the National Research Council for assistance, and the Subcommittee on Medical Food Requirements was appointed within the Division of Medical Sciences. This committee was organized in April, 1943. Its recommendations were published in the *Journal of the American Medical Association*¹ in October and were accepted by the Office of Price Administration on March 30, 1944, thirteen months after the advent of the rationing program. However fine the mills of the gods may grind, they certainly grind exceedingly slow.

The subcommittee was fortunate in having had the precedent of the Special Diets Advisory Committee of the British Medical Research Council to guide it to some degree. The British program worked well, but certain fundamental differences existed between the British situation and our own. Great Britain depends largely on the importation of food, and during the war the Ministry of Food owned some 98 per cent of the imported supply. Furthermore, Great Britain is geographically small and thickly settled, with relatively uniform dietary habits. The United States, on the other hand, is primarily a food-producing country with a mixed

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 22, 1946.

†Chairman, Committee to Aid the Regional OPA, Massachusetts Medical Society.

hoarseness (The opportunity for a pun is obvious, but a pun is still considered the lowest form of humor.) Other requests included 1 pound of processed foods and 31 of meats and fats a week for a patient with hemiplegia, 40 pounds of processed foods and 12 of meats and fats for another with hypertension, 31 pounds of processed foods and none of meats and fats for a pyelonephritic patient with renal calculi, 9 pounds of processed foods and no extra meats and fats for a patient with duodenal ulcer, and 12½ pounds of meats and fats and none of processed foods for another with the same disease. Too often, no rhyme or reason could be discovered for the types or quantities of foods solicited.

This particular committee of the Society believed that its functions were to advise and not to police, to make exceptions to any specific policy when a reasonable doubt seemed to exist in any given case and to err on the side of possible indulgence to prevent injustice, and yet to protect the interests of the majority. Our experiences also led us to believe that actually few persons could not have subsisted comfortably on their basic allotments, procured with reasonable intelligence, regardless of the disease.

Our observations further taught us that a danger is inherent in bureaucratic institutions, a propensity that must be curbed to regiment one's fellows and to derive satisfaction and a sense of duty done from the exercise of authority.

* * *

Certain conclusions based on our food-rationing experiences seem warranted. It is apparent that many, perhaps the majority of physicians are not well grounded in dietetics, particularly regarding the role and the quantitative application of the diet in disease. This fault is presumably one of basic medical training. At the same time, we must face the probability that wide gaps still exist in the available knowledge of the role that diet plays in disease. It is conceivable that some of the ideas that tradi-

tion has fixed strongly on us may at some future time be discredited. We must moreover accept the possibility that pressure that is hard to resist is not infrequently put on the physician to induce him to sign statements that may not entirely accord with his better judgment.

Many persons who are faced with the responsibility of marketing have little knowledge of this domestic function, of food values or of the planning of diets. Much more assistance should be made available to the public, nutrition centers should be one of the important municipal enterprises.

The value of fortified oleomargarine as an acceptable table fat has been demonstrated, and it should be allowed by law to compete on more nearly equal terms with other fats used for the same purposes. During the rationing period this committee accepted the point value of margarine as its standard for table fats.

There is justification for believing that occupational and perhaps other qualifications should be allowed to affect strict rationing principles. In the face of total war, the policy of lavish provision for military personnel at the expense of the civil population deserves reconsideration.

The war and subsequent events have brought to the fore some of the problems that had previously existed concerning the dangerously large and growing world populations and their source of food. The consumption of an abundant food supply by favored groups and nations while others starve may never again be permitted, some degree of food rationing will be perpetually necessary if Nature's stern laws are to be held in abeyance, and if succor is to be given those who else would fain have filled their bellies with the husks that the swine did eat.

advising on the rationing difficulties of the four New England states that had failed to provide themselves with committees of their own. In August, 1944, it became, in addition, part of a larger committee organized to aid the War Food Administration in controlling the cream situation.

In the meantime, however, local committees were being appointed in strategic localities, largely through the good offices of the War Participation Committee of the Society, until eventually Brockton, Brookline, Haverhill, Lawrence, Lowell, New Bedford, Newburyport, Pittsfield, Springfield and Worcester were thus more or less autonomously served. As time went on, Maine, New Hampshire and Connecticut also established medical panels along a similar pattern. The Rhode Island office had been working successfully with the state medical society since the early days of rationing.

The population of Massachusetts at the time of the 1940 census was 4,374,000. Of this population, 13,500 persons were known to be receiving supplemental rations in September, 1944, and 18,898 in September, 1945, or less than 0.5 per cent. The rate of distribution of these extra rations showed the highest population percentage thus favored to come from cities of 15,000 to 25,000 population, with 0.5 per cent of the inhabitants in the privileged class, and the lowest receiving second helpings to come from cities of 5000 to 10,000, with only 0.2 per cent. Most of the acute rationing problems seem also to have come from the cities with 15,000 to 25,000 population. The Regional Office, from May, 1943, through August, 1945, processed 16,290 applications, of which about half were individually reviewed by the committee and the rest according to suggestions emanating from the committee.

It is also a matter of interest to learn that, after the virtual end of rationing, when the affairs of most of the local boards had been wound up, over 2000 unsuspected beneficiaries of extra sugar allotments turned up at the regional office for renewal of their unauthorized certificates.

Various factors in the food-rationing program created confusion and added to the difficulties of its administration. For those not infrequent persons who are ordinarily unable to clear the hurdle of counting their change after a purchase, the use of two forms of currency, points and pence, to be applied to pounds and ounces was almost more than could be endured. The frequent shifting of point values as different types of food became more or less available affected the extra allowances that were necessary to balance the various diets of "medical necessity." The inclusion of meats and fats on the same ration lists may have simplified the book-keeping of the program, but it made no sense when the balancing of a diet was contemplated. Life may simply have been rendered more piquant to the average housewife when she was made to choose between beefsteak and butter, but the two forms of

food had quite different meaning for the diabetic patient.

The one distinguishing feature of all processed foods was that they had to be preserved in some way, from canning to drying, and with fresh fruits and vegetables usually available, it soon became apparent that their value and desirability was rather an economic than a medical one. Actual justice based on individual merits was scarcely more evident in rationing than under a free economic system alone. The infant from the moment of birth, as a potentially free citizen of a country determined to be free, was given the same number of ration points as a manual laborer or a seasoned politician. The family of twelve had infinitely more variety in its point purchasing power than the spinster alone in her one-room apartment. The poorest farmer could live better than the richest banker, if the latter refused to patronize the black market.

Various abnormal physical conditions recurred as bases for extra-diet requests, and this committee believed that it was justified in departing, not infrequently, from the path marked out by the Subcommittee on Medical Food Requirements. Consideration was given to severe anemias of any type, to ulcer either recently postoperative or with recent hemorrhage, to allergy if specific clinical manifestations substantiated the request, to pregnancy in the latter half of the period of gestation, to rheumatoid arthritis with hypoproteinemia, weight loss or anemia, to malaria only on the basis of severe anemia and to demonstrated hypoproteinemia. Hypoglycemia, on the basis of recent advices, was usually considered to justify extra protein rations, rather than extra sugar. Nephrolithiasis came to be used as a basis for extra protein to produce an acid-ash diet, and the Schemm high-protein diet was recognized as of value in the treatment of heart disease with congestive failure. Whenever a question of policy arose, it was the custom of the committee to consult with recognized authorities. It was frequently necessary to return applications for more specific information than had been given—for example, with the patient who was stated to be allergic to all unrationed foods.

Extra evaporated milk, on the red-point list with meats and fats, was frequently requested for infants but was rarely granted, since the basic allotment of points covered the recognized milk requirements for normal babies.

Rations were requested at one time or another for practically all known diseases and in all imaginable quantities. The program, indeed, furnished the ideal example of the universality of headache as a symptom of all diseases—only it was the committee that had the headache. Such requests were made as the following: 14 pounds of meat a week for a child for normal growth, 7 pounds for the treatment of frequent colds, 4 pounds for the treatment of heartburn, and 2 pounds for the treatment of

from various prisons have also repeatedly shown a high prevalence of tuberculosis among such groups. The confinement and frequent overcrowding of these institutions offer an excellent opportunity for spread of the disease, and since many prisoners are later discharged to their homes and community, the dangers are obviously great.

Despite an unprecedented high average income, there are still many people in the low-income group, and it appears that the Negro remains at the bottom of the scale. The result is that among Negroes of twenty to thirty-five years of age, 1 in every 3 deaths is due to tuberculosis. Surveys have also shown that there is a high prevalence of tuberculosis among the Chinese and Polish groups. Poverty and tuberculosis go hand in hand, and a family fairly well off before tuberculosis strikes is often reduced to dependency when the wage earner enters the sanatorium.

It is an accepted fact that decent housing, an adequate diet and just wages for acceptable standards of living are necessary to keep down the tuberculosis rate. There is no doubt that a potent factor in the remarkable reduction in the tuberculosis mortality in this country over the past fifty years is the improved living conditions that have prevailed. If the disease is to be further eradicated, greater effort will have to be made to abolish slum areas and crowded tenement districts. A geographic survey of Boston undertaken by the Health Department showed that the highest incidence of tuberculosis is found in the crowded districts of the South End, West End, Roxbury and South Boston.

Industry must play its part if a reduction in the morbidity and mortality of tuberculosis is to be realized. A pre-employment examination, including an x-ray film of the chest, should be required. Well established standards for ventilation, sanitation, health education, personal hygiene and fair wages should be enforced.

The tremendous economic and financial burden on the taxpayer when long hospitalization is involved is not fully realized by the general public. According to the National Tuberculosis Association, the economic loss to the family and community, in addition to the cost of treatment, amounts to \$10,000 for each death from tuberculosis. The number of deaths in the community multiplied by this figure will give the financial loss from tuberculosis during any year. Case finding is a sound investment on the part of any community. The earlier the case is diagnosed, the shorter the period of hospitalization. In addition, the number of cases will be definitely reduced, for the early segregation of the patient prevents spread of the disease to the family and the community.

The opportunity of practicing physicians to find cases of tuberculosis is unquestionably greater than that of any agency, in view of the many patients

that pass through their hands. It is regrettable that, time and again, patients are admitted to sanatoriums with far advanced tuberculosis after having been under treatment for months for chronic bronchitis. It is a safe policy for the physician to insist on an x-ray film of the chest in every case in which a patient's cough persists for more than two weeks. There are some physicians who, despite a cough lasting for months, will not order an x-ray examination until abnormal sounds are heard in the chest. Any physician who waits to make a diagnosis of tuberculosis by auscultation imposes a grave responsibility on himself—9 out of every 10 cases by that time are in the advanced stage. It is no credit to a physician when a patient or the family suggests, and even sometimes demands, an x-ray film of the chest after numerous cough mixtures have failed and then to find, to his surprise, existing tuberculosis.

Again, the physician will find it advantageous to insist on an x-ray examination of the chest every six months on all diabetic patients. The high incidence and rapid spread of tuberculosis in diabetic patients are well known. It is further recommended that a chest x-ray film be taken in all cases of pneumonia approximately three months after the patient has fully recovered from the illness, since it has been shown on numerous occasions that an attack of pneumonia has been the responsible agent in lighting up an old inactive tuberculous lesion.

Any board of health has a responsibility for those unable to obtain the services of a physician and also a responsibility to the physician to provide diagnostic facilities. Boston is fortunate in having an efficient and well managed health department that provides examination of the sputum, tuberculin testing, x-ray study and consultation services. This service is free, and the physician should make every possible use of it. The inability of the general practitioner to recognize the disease in the early stage seriously retards the eradication of tuberculosis.

The physician should be educated to the necessity of reporting all cases of tuberculosis to his board of health as soon as the diagnosis is established and should not wait to do so on the death certificate. Early notification is of the greatest importance in any control program. During the past year there were 411 fatal cases of pulmonary tuberculosis in Boston. Of this number 96, or 20 per cent, were reported after death. It does not take much imagination to see that no program will progress if 20 per cent of the cases of tuberculosis are reported after death.

Those engaged in tuberculosis work have long realized the deficiencies in the training of family physicians in the diagnosis and treatment of tuberculosis. A regularly scheduled course of lectures should be made available to all practicing physicians in the community. Such schedules can best be arranged

TUBERCULOSIS CASE FINDING*

JOHN A. FOLEY, M D,† AND JOHN B. ANDOSCA, M D ‡

BOSTON

THE continuous decline in the mortality and morbidity from tuberculosis since the beginning of the century has been most gratifying. Comparison of present rates with those of preceding years has engaged the attention of all public-health and allied workers.

Less publicized and perhaps less understood generally are the facilities now available for case finding as compared with those of twenty-five years ago. At that time no well organized plan or agencies for intensified case finding existed. The major question was not where or how to look for additional cases but what to do with the known cases. The hospital beds were far from adequate. The case-finding work that was done in some of the larger communities consisted for the most part in physical examination of the chest and laboratory examination of the sputum. Few, if any, clinics were provided with or had access to x-ray equipment, and the equipment itself had not reached the stage of development that made x-ray study of the chest in appreciable numbers of cases practicable. Even when x-ray service was available, it was always employed to substantiate a diagnosis already confirmed by physical or laboratory examination. As the knowledge for the care of tuberculosis increased and improvement of x-ray equipment developed, interest in case finding among contacts of known cases began to be manifest.

For a period of several years the tuberculin testing and x-ray examination of thousands of children and high-school students was perhaps the most vigorously promoted phase of the program of tuberculosis control. The splendid attention children received as a result of this activity yielded valuable information and focused the investigation on what is known as primary tuberculosis. These studies showed the remarkable ability of the majority of children to bring primary tuberculosis under satisfactory control.

Increasing interest in the control of tuberculosis in college students is due in large part to the co-operative efforts of the Tuberculosis Committee of the American Student Health Association and college authorities. The number of colleges and universities with case-finding programs has increased from six to over three hundred in the past fifteen years. As a result of such routine programs in colleges, between 700 and 900 new cases of tubercu-

losis have been diagnosed annually during the past several years.

The aim of any well managed and effective control program is early case finding by mass x-ray examination, which has been of tremendous value in the study of thousands of workers in industrial plants and business offices. A splendid example of how industry and labor can co-operate in early tuberculosis case finding was the recent mass x-ray examination of 100,000 fur workers and their families in New York City. The survey was the culmination of months of intensive educational work. The unions mailed posters to all the shops, distributed handbills among workers and included information in every meeting notice. If this record can be accomplished in one industry in a community it can certainly be duplicated in others.

The release of information on tuberculosis by Selective Service boards after mass x-ray study of all inductees showed what can be accomplished in discovering early tuberculosis. The survey pointed out that 90 per cent of the men rejected for tuberculosis had minimal disease, whereas almost 90 per cent of the patients admitted to most of the sanatoriums in this country have advanced disease.

The recent appreciation of the fact that adults, rather than children, are chiefly responsible for the spread of tuberculosis is why control programs are focused on older age groups. Public-health laws should insist on the mass x-ray examination of all schoolteachers, food handlers and domestics—a surprising number of food handlers, such as cooks and waiters, are admitted to sanatoriums. Tuberculosis is found more frequently in certain occupations than in others. The danger of silicosis and tuberculosis is well known and much has been done to control the hazard of silica dust.

Student nurses and physicians are often exposed to massive infection in their daily duties. This problem has only recently been recognized in its relation to the general hospital or to the institution for the mentally ill. Every patient admitted to a general hospital should have an x-ray examination of the chest. In this manner, many new cases of tuberculosis could be discovered. If these cases could be detected on admission, it is quite reasonable to believe that the prevalence of tuberculosis among medical students and nurses would be greatly reduced.

X-ray films of inmates of mental hospitals should be taken from time to time, for recent reports have shown a high incidence of tuberculosis, these patients are a source of extreme danger not only for other inmates but also for the attendants. Surveys

an appropriate loss in weight. Apparently, in many cases, such loss of weight is masked for as long as nine or ten days by a compensatory gain in body water, which is eventually lost, revealing the true body weight. There is also little evidence for the popular view that obese persons have a more efficient digestive mechanism that enables them to extract from their food a higher percentage of nutrient material.

It has also been suggested that adiposity is caused by a hereditary trait of the adipose cells by which they are enabled to accumulate excessive amounts of fat and retain it despite starvation. This suggestion has been disposed of by Newburgh.⁶ Obese persons were shown to be able to release fat into the blood when placed on a starvation diet, and the fasting respiratory quotients in fat persons were found to be lower than those in normal controls, indicating that fat was being used for energy purposes. According to Conn,⁷ abnormalities of the endocrine system, which affect adipose tissues, are more closely related to distribution than to excessive accumulation of body fat. The search for metabolic aberrations that could lead to obesity has therefore not been fruitful. The accumulation of fat appears in most cases to be the result of an overall intake of energy that has exceeded the total dissipation of energy by the body, with the result that the excess energy has been stored in the form of fat. The fundamental fault therefore seems to be largely an excessive desire for food. This factor is suggested also by the careful study of Danowski and Winkler⁸ on the long-term management of obese patients. Neither the central nervous system nor endocrine factors were significantly involved in the 141 patients included in their study, and in most cases it was found possible to effect weight reduction by restriction of the caloric intake. In almost all cases, however, there was a failure to maintain weight reduction, and the authors emphasized the difficulty of effecting significant changes in the dietary habits of their patients.

A number of recent studies throw light on the important question of overeating or, for that matter, undereating. Basically, eating is instinctive, and it is not surprising, therefore, that there are strains of mice in which overeating and adiposity are hereditary and appear to be associated with a single gene that is identical with the one responsible for yellow color in mice.⁹⁻¹⁰ Severe and prolonged insulin hypoglycemia in mice leads to overeating and obesity,⁷ and hypoglycemia in man^{11, 12} also results in excessive eating and gain in weight. In 5 of the 6 cases presented by Rennie and Howard¹¹ a gain in weight was a striking phenomenon — the result of frequent eating to relieve the hypoglycemia.

One of the most fruitful approaches to the problem of obesity is the study of its association with the hypothalamus. The earlier experimental workers in this field were more impressed with the role of

the hypophysis, and a measure of evidence still implicates this organ. Thus, in the experiments of Heinbecker, White and Rolf¹³ on experimental obesity in the dog, it was found that either removal of the hypophysis or production of a lesion of the hypothalamus, resulting in partial or complete destruction or denervation of the paraventricular nuclei of the hypothalamus, caused obesity. The additional bilateral destruction of the supraoptic nuclei enhanced the rate of development of the obesity. The maximum degree of obesity followed a properly placed hypothalamic lesion without removal of the hypophysis, but following such a lesion a diminution and degeneration of the basophil cells of the hypophysis occurred. The enhanced rate of development of obesity occurring with damage to the supraopticohypophyseal system is of interest inasmuch as this nervous pathway is responsible for the control of the antidiuretic-hormone-forming tissue of the hypophysis and because diabetes insipidus resulted when it was cut. Obesity may, however, be produced without the participation of the hypophysis, as shown by the experiments of Hetherington and Ranson,¹⁴ who placed lesions in the ventromedial hypothalamic nuclei and later hypophysectomized the animals. After the usual interval of three to six weeks following the hypothalamic operation, all the hypophysectomized animals became progressively fatter until a high degree of adiposity was attained. In subsequent experiments reported by Hetherington,^{15, 16} hypothalamic obesity was produced in rats already displaying chronic hypopituitarism as the result of hypophysectomy. During a period of approximately eleven weeks after removal of the hypophysis, no signs of obesity appeared, but shortly after hypothalamic lesions were made, obesity began to appear.

Brobeck and his co-workers¹⁷ have shown that the essential cause of the gain in weight of hypothalamic animals is an increased food intake, although there may be an associated reduction in activity. When hypothalamic rats are pair-fed, that is, given only the amount of food taken by a normal rat, they do not gain in weight, but become obese only when they are given access to an unlimited supply of food. The characteristic change in the food habits of these animals was that they voraciously attacked their food and ate large quantities in a short time, comparable to the episodes of bulimia observed by Brügger¹⁸ produced by electric stimulation of the hypothalamus. Wheatley¹⁹ noted that cats with hypothalamic lesions became fat, as did monkeys studied by Ruch, Schenken and Patton.²⁰

By analogy with the sham rage of decorticate and hypothalamic cats noted by Bard²¹ and other workers, it might be postulated that excessive eating in this condition represents the release of lower mechanisms from control by hypothalamic nuclei and that, in turn, these centers are released from inhibitory influences from higher levels of the brain.

through the district medical society. It is safe to say that a good number of general practitioners do not even know what the inside of a sanatorium looks like. The physician should certainly avail himself of the opportunity to visit the nearest sanatorium from time to time and see for himself what is being done for the patient with tuberculosis.

Medical schools should avail themselves of the best and most effective method of teaching the essentials of diagnosis and treatment of tuberculosis. It is unfortunate that the great majority of graduates of medical schools do not have a sufficient understanding of tuberculosis. This situation seems to be due to the fact that the medical graduate is often told that tuberculosis is a waning disease that will completely disappear in a few years, medical students twenty-five years ago heard the same story. There is no doubt that tuberculosis is still the most serious health problem confronting any state or community. One cannot overlook the fact that there are still about 500,000 cases in the United States, that tuberculosis is the leading cause of death between the ages of twenty and forty

and that on the average nearly 60,000 persons die of tuberculosis every year.

The public must be constantly and increasingly educated in the danger and contagiousness of tuberculosis. When the disease strikes a member of a family, interest is aroused, but even then the members frequently fail to heed the danger that threatens them. The motion-picture industry could and should play an important role in the production of films available not only for teaching purposes but also for impressing on the public the value of tuberculosis case finding.

* * *

It is obvious that the crux of any program of tuberculosis control is early case finding by mass x-ray study and immediate segregation of the patient until he is well enough to return to his family and community. If a reduction in the mortality and morbidity from tuberculosis is to be achieved, the full support and co-operation of the general practitioner, the public, industry and public-health agencies are absolutely essential.

MEDICAL PROGRESS

PHYSIOLOGY*

HEBBEL E. HOFF, M.D.†

MONTREAL, CANADA

A CONSIDERATION of current publications that describe physiologic investigations carried out under the impetus of war suggests that, in this field as in others, greater progress was made in the application of known basic principles than in the discovery of new material. This is not, however, entirely the case. Thus, the pharmacologic screening of thousands of previously untested toxic compounds for potential value as chemical-warfare agents has uncovered many that hold promise as therapeutic agents or as tools in future physiologic investigations.¹ The great practical advance in the production of radioactive material will certainly be of inestimable value in the study of the biologic relations of these substances.²⁻⁴ Undoubtedly, the war has also hastened the recognition of the essential unity of psychologic and physiologic processes and the appreciation of the importance of psychosomatic relations in disease. Some of these are briefly reviewed.

OBESITY

The recent report by Levy, White, Stroud and Hullman⁵ on the increased incidence of cardio-

vascular disease associated with obesity in a study of 22,000 officers in the Army adds further evidence to the accumulating data pointing toward the unfavorable influence of obesity on length of life.⁶ It may of course be argued that obesity and cardiovascular disease represent two manifestations of a single etiologic factor operating through some genetic or psychosomatic mechanism and that control of the obesity has less than the expected influence on the cardiovascular system. The common-sense view of the matter, however, seems to be that since obesity requires an increase in metabolism to maintain itself and therefore demands an increased cardiac output, it is only reasonable to suppose that this constant additional strain proves harmful in the long run, especially when for some other reason the efficiency of the cardiovascular system is reduced. Metabolic studies in obese patients tend to discount the presence of any important alteration in metabolism in the great majority of cases.^{6,7} Obese patients in general do not show a lower energy expenditure than normal persons of the same height, age and sex, on the contrary, their total expenditures of energy are greater. If they are placed on a low-calorie diet and their weight determined over a long period, they do not fail to show

Cutting²⁸ and Spiegel and Oberndorf³⁰ At the least, the evidence they present makes it impossible to accept the earlier conclusion of Daniels³⁹ that the manner in which such patients faced the problems presented by their infirmity indicated that they were of a stable nature. Apparently, other aberrations of the sleep mechanism may be involved in much the same manner. Thus, Ingram, Barris and Ranson⁴⁰ were able to produce catalepsy—a somnolent state characterized by loss of voluntary motion and sensibility and a peculiar plasticity of the skeletal muscles—by lesions of structures in the neighborhood of the mammillary bodies, such as the posterior hypothalamic nucleus, the supra-mammillary area, the lateral hypothalamic area and the region caudal to the mammillary body. A somewhat similar clinical condition called sleep paralysis in which, on awakening, consciousness returns some seconds before the return of voluntary motor power seems to occur in persons intensely disturbed by confusion in emotional direction.^{41, 42}

It is to be understood that the hypothalamus can be called a "center," so far as such functions as sleep and appetite are concerned, only in the sense that it serves as a final common path for such activity and not as the center in which activity originates, and that essentially similar results are obtained by lesions that interrupt pathways between the hypothalamus and receptor organs, by damage to the hypothalamus itself⁴³ and by lesions interrupting pathways between the cortex or other structures and the hypothalamus⁴⁴ or psychologic disturbances involving eventually the same pathways. Even when the basic lesion is anatomic, as in a case quoted by Aring and Engel,⁴⁵ psychotherapy has an important role to play, but on the other hand, medical therapy has an equally valuable role to fill when the etiology is of purely psychologic origin as illustrated by the success of amphetamine (Benzedrine) sulfate in the treatment of narcolepsy and obesity.⁴⁶

TREATMENT OF PEPTIC ULCER

The salient features of peptic ulcers might be outlined almost exactly as the preceding topics.⁴⁷⁻⁴⁹ In experimental animals and in man, gastrointestinal ulcers are sometimes produced by lesions of the hypothalamus. Cortical lesions also cause disturbances in the gastrointestinal tract, presumably by interruption of fibers passing to the hypothalamus. Such lesions upset a normal level in parasympathetic balance, leading to excessive secretion and motility and, perhaps, excessive vasoconstriction in the mucosa resulting in local anemia that renders the mucosa digestible by its own juice. A vicious circle is set up by the feeding back into the central nervous system of abnormal impulses from the gastrointestinal system arising either from pain or from hypermotility, which, in turn, intensify the nervous imbalance that was the primary cause of the ulceration. The situation thus becomes autonomous—

that is, capable of continuing after the precipitating factor has disappeared.⁵⁰⁻⁵² In man the same neural pattern may be involved in a neurotic reaction to produce and maintain gastrointestinal lesions. Medical treatment is of value as an adjunct of psychotherapy by helping to stop the vicious circle by interrupting it at some peripheral point. The psychoanalytic concept of the etiology of peptic ulcers is reviewed as follows by van der Heide.⁵³

Under the influence of certain unhappy experiences, interfering too much with a natural development, a child can be forced to fall back in its emotional maturation. This may sometimes increase such wishes as to be cared for, to be loved, to depend on others, to receive and—if thwarted—to take aggressively (regression to oral receptiveness and oral sadism). Whereas the ego reacts to such tendencies with feelings of inferiority and guilt, these are repressed from consciousness, sometimes under seal of a strong overcompensation, manifest as an independent, efficient, later responsible and giving attitude in life. This type of "conflict-solution" was regularly found in the gastric patients whose unconscious longing for care, love and dependence could not be concealed from the analytic observation. Next to the described internal reaction, sometimes external factors were found to be capable of maintaining a fatal frustration of those infantile cravings. The latter, obviously, once in life are perfectly gratified, namely, at the time of being nursed, when almost indistinguishably love and food are abundantly offered. Alexander states, "The wish to be loved becomes emotionally associated with the wish to be fed." If wishes for care and dependence are now strongly repressed, we may assume that these easily activate, or rather are "converted into" the desire to be nourished, which as a continuous unconscious psychic stimulus, influences the secretory, muscular and vascular condition of the stomach by means of the vegetative nervous system until it behaves "as if it were taking or were about to take food." Such chronic functional gastric disturbances, besides being likely to cause neurotic stomach complaints, appear to be of essential importance for the development of gastric and duodenal ulcers.

These factors are illustrated in the history of 2 cases reported by van der Heide in which the stomach complaints preceding the occurrence of an ulcer arose when the incongruity between the overt behavior (struggle and ambitious efforts for accomplishment) and the repressed longings for dependence became excessive.

In great measure because of Cushing's⁵⁴ concept of excessive vagotonia as the principal precipitating factor in the etiology of peptic ulcer, attention has recently been turned to the surgical section of the vagus nerve as the most effective means of arresting this hyperactivity.⁵⁵ A recent report by Thornton, Storer and Dragstedt⁵⁶ strongly suggests that the most important etiologic factor in the genesis of ulcer is the continued hypersecretion of acid during the night. They found that this hypersecretion is almost entirely neurogenic in character and is greatly reduced by section of the vagus nerve. The empty stomach of ulcer patients also displays a hypertonicity and hypermotility, with exaggerated hunger contractions, and these functions return toward normal after bilateral vagotomy.

On purely theoretical grounds atropine might be expected to be as effective as surgical section of the nerve, but this expectation is not fulfilled. This may

with the production of a similar condition Ferencz et al²² noted, in fact, that marked obesity developed in two decorticate cats kept alive for over a year

The only significant metabolic change noted in hypothalamic animals has been an abnormally large elevation of the respiratory quotient appearing after the administration of glucose,^{23, 24} but it appears that this alteration is secondary to the altered eating habits of the animals and that when normal animals are trained to eat in the same fashion they show a similar carbohydrate response

Most interesting is the observation that syndromes closely resembling those produced by anatomic lesions may appear as the result of psychologic stresses in the absence of an anatomic substrate. Thus, it is impossible to find frank hypoglycemia in all cases of so-called "hypoglycemic fatigue," although an altered sugar-tolerance curve like that of frank hypoglycemia may be seen. In a number of these patients the personality make-up was one of a conscientious, hard-working but dependent person in whom the difficulty was precipitated by increased responsibilities and withdrawal of protecting influence. Fatigue thus served to excuse the patient for nonperformance of tasks that had become distasteful, but it also served to make matters worse and thus set up a vicious circle of increasing fatigue and increasing distaste for work. At times, in such circumstances, medical treatment broke the vicious circle by reducing fatigue and was therefore an essential counterpart of psychotherapy

Psychologic factors may also be recognized in the precipitation or intensification of attacks in patients in whom some underlying disease exists, as in the cases reported by Meyer, Bollmeier and Alexander,²⁵ in which a definite correlation between the emotional status and the quantity of sugar appearing in the urine of diabetic patients could be made out, and in the case reported by Romano and Coon,²⁶ in which attacks of hypoglycemia were produced by emotion in a patient who was later found to have a pancreatic tumor. A much closer approximation to actual anatomic syndromes was observed in certain cases of narcolepsy, discussed below, in which the syndrome of abnormal sleep, obesity and polyuria may develop on a purely psychologic level.²⁷⁻³⁰ This also occurs in anorexia nervosa, which closely simulates Simmonds's disease.³¹⁻³³ It has been postulated that rejection of food is an expression of fear of pregnancy based on childish concepts of oral impregnation. It is interesting that in most of the cases of anorexia reported, periods of rapid weight gain, sometimes to the point of obesity, and of compulsive eating of large quantities of food have occurred along with excessive drinking of water. It is clear that appetite and eating represent a fundamental primary instinctive drive to which an early sexual association is attached. In

addition, eating is one of the first ways in which an infant is brought into association with other persons, and it develops, therefore, into an important medium for social expression. It is not to be wondered at that eating becomes much more than a process whereby the body is supplied with an adequate number of calories and vitamins

SLEEP

The sleep mechanism is another example of an essentially instinctive mechanism — heavily weighted with emotional and social values — that may become disturbed at anatomic, physiologic or psychologic levels. It is well established that on the anatomic level the hypothalamus is intimately associated with sleep and that increased somnolence can be caused by damage to the hypothalamus in regions that on stimulation produce hyperactivity.^{34, 35} It has also been observed that pathologic sleep may be associated with lesions in the cortex without invasion of the hypothalamus and in the absence of increased intracranial pressure.³⁶ Such observations led Davison and Demuth³⁶ to the conclusion that some fibers for the control of sleep originated in the cerebral cortex, especially in the hippocampal, cingular, premotor and temporal convolutions, and that injury to these areas or to their connections with the hypothalamus occasionally caused pathologic sleep. The psychologic value of sleep is manifest at a number of levels. Superficially it affords rest and recuperation, on a deeper plane, it furnishes a means of escaping from reality and represents a return to intrauterine life or even a type of death.³⁷ It thus affords a means of unconsciously satisfying forbidden wishes without experiencing conscious guilt. These concepts are clear even in the pre-Freudian psychology as can be seen by the following translation from Burdach's³⁸ treatise published over a hundred years ago

Periodicity ought thus to consist of an alteration of propulsion, which leads to development, and of retrogression, which leads backward toward the embryonic life. In fact, life tends to progress, but it also attempts to remain the same, and this latter tendency is the actual cause of all periodic retrogressions. Since the most general attribute of the organism is to conserve itself, — that is to say, to maintain itself by its own activity, — the primordial form of existence ought to be that which is always dominant, that which attempts to maintain itself throughout life. But this enters into conflict with the purpose of life, which can only be attained by progressive development, and the hindrance which it thus experiences permits it to manifest itself only with a periodic character. Periodicity is thus the expression of the conflict between development, expressed by exhaustion, and the return to the primordial state, which is manifested by contraction

Periodic return is therefore a suppression of antagonisms, an effacement of differences during which life reunites its forces for a new step along the road of development. Just as Geryon, son of the earth, felt the return of his strength when he touched the breast of his mother, so also the organism is rejuvenated in its return to the primordial state. The direction from within outward is a finite force that is dissipated by the very act of its own manifestation, and it renews its vigor only if the life withdraws into itself

The psychogenic nature of narcolepsy seems to be well established in the cases reported by Davison,³⁷

CASE 32491

PRESENTATION OF CASE

A twenty-nine-year-old housewife entered the hospital because of paraplegia.

Three years before entry, she had two attacks of pain half way down the posterior aspects of both thighs but severer on the left than on the right. Each attack lasted about two days. The patient then remained asymptomatic until two years before entry, when she had several similar attacks. At that time the patient saw a doctor, who removed the tonsils, the episodes of pain continued, however. A year and a half before entry the patient had a particularly severe attack precipitated by an attempt to catch herself while falling, in addition to radiating down the thighs, there was pain low in the back for the first time. The pain was aggravated by coughing, sneezing and straining and was worse when the patient was sitting or lying down than on standing. She was unable to bend over to tie her shoes. She also complained of a feeling of pressure in the bladder and of some nocturia.

Fourteen months before entry the patient had been operated on at another hospital for rupture of the intervertebral disk between the fourth and fifth lumbar vertebrae on the left. Following the operation she continued to have low-back pain on coughing or straining. The leg pains subsided but returned a few weeks later. Seven months later the pain had extended into the calves and was so severe that she remained in bed for two months, getting up only to go to the bathroom. Then she gradually undertook more activity, but the legs were weak and felt as if they were about to buckle. Five months before entry she began to have difficulty in controlling the bladder and subsequently was occasionally incontinent of urine. She also noticed numbness over both thighs from the iliac crests to about 15 cm above the knees. This and the incontinence subsided spontaneously after six weeks. The weakness of the legs progressed, however, and four months before entry the patient was able to walk only with a cane and the help of another person. She also had severe pain in the lower

lumbar region, sometimes radiating up to the costal margins and aggravated by straining but not coughing. Bladder and bowel functions were good except for constipation, which was controlled by laxatives.

Except for marked tenderness over the lower lumbar spine, the abnormal findings on physical examination were confined to the lower extremities, which were pale and cold. All motions of the feet, legs and thighs were extremely weak, there was no complete paralysis. Both knee jerks and the right-ankle jerk were absent, there was a weak left-ankle jerk. The plantar reflexes were absent. Sensation was impaired below the groins.

The temperature, pulse and respirations were normal. The blood pressure was 110 systolic, 80 diastolic.

Examination of the blood showed a white-cell count of 8400, with a hemoglobin of 12.4 gm. The serum nonprotein nitrogen was 27 mg per 100 cc. The urine was normal except for a + test for albumin.

On x-ray examination the pedicles of the second and third lumbar vertebrae on the right could not be clearly seen and appeared to be partly destroyed. In the lateral view there was a slight deformity—suggesting erosion—of the posterior border of the body of the second lumbar vertebra. A puncture at the third lumbar vertebra produced slightly hemorrhagic xanthochromic fluid, which clotted on standing. There was no rise in pressure on jugular compression. The total protein of the fluid was 5880 mg per 100 cc. Five tenths of a cubic centimeter of Pantopaque in oil was injected, and on lowering the head end of the table this was arrested opposite the upper margin of the third lumbar vertebra.

On the sixth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. R. EUSTACE SEMMES* The clinical picture three years before admission suggests a ruptured intervertebral disk in the lumbar region, from the facts that the patient had intermittent pain down the legs, which had increased suddenly on some strain of the back, and that it was difficult for her to tie her shoes. Also, the pain was aggravated by coughing and straining. Several things, however, make one stop, look and listen before assuming that she had a ruptured intervertebral disk. In the first place, although one not infrequently sees a patient whose pain was originally in the leg, without involvement of the back, such a situation is unusual when the pain is on both sides. Another point is that the pain was less when the patient was standing, whereas most patients with ruptured intervertebral disks obtain relief from lying down. The loss of control of the bladder also makes one

CASE 32491

PRESENTATION OF CASE

A twenty-nine-year-old housewife entered the hospital because of paraplegia.

Three years before entry, she had two attacks of pain half way down the posterior aspects of both thighs but severer on the left than on the right. Each attack lasted about two days. The patient then remained asymptomatic until two years before entry, when she had several similar attacks. At that time the patient saw a doctor, who removed the tonsils, the episodes of pain continued, however. A year and a half before entry the patient had a particularly severe attack precipitated by an attempt to catch herself while falling, in addition to radiating down the thighs, there was pain low in the back for the first time. The pain was aggravated by coughing, sneezing and straining and was worse when the patient was sitting or lying down than on standing. She was unable to bend over to tie her shoes. She also complained of a feeling of pressure in the bladder and of some nocturia.

Fourteen months before entry the patient had been operated on at another hospital for rupture of the intervertebral disk between the fourth and fifth lumbar vertebrae on the left. Following the operation she continued to have low-back pain on coughing or straining. The leg pains subsided but returned a few weeks later. Seven months later the pain had extended into the calves and was so severe that she remained in bed for two months, getting up only to go to the bathroom. Then she gradually undertook more activity, but the legs were weak and felt as if they were about to buckle. Five months before entry she began to have difficulty in controlling the bladder and subsequently was occasionally incontinent of urine. She also noticed numbness over both thighs from the iliac crests to about 15 cm. above the knees. This and the incontinence subsided spontaneously after six weeks. The weakness of the legs progressed, however, and four months before entry the patient was able to walk only with a cane and the help of another person. She also had severe pain in the lower

lumbar region, sometimes radiating up to the costal margins and aggravated by straining but not coughing. Bladder and bowel functions were good except for constipation, which was controlled by laxatives.

Except for marked tenderness over the lower lumbar spine, the abnormal findings on physical examination were confined to the lower extremities, which were pale and cold. All motions of the feet, legs and thighs were extremely weak; there was no complete paralysis. Both knee jerks and the right-ankle jerk were absent, there was a weak left-ankle jerk. The plantar reflexes were absent. Sensation was impaired below the groins.

The temperature, pulse and respirations were normal. The blood pressure was 110 systolic, 80 diastolic.

Examination of the blood showed a white-cell count of 8400, with a hemoglobin of 12.4 gm. The serum nonprotein nitrogen was 27 mg. per 100 cc. The urine was normal except for a + test for albumin.

On x-ray examination the pedicles of the second and third lumbar vertebrae on the right could not be clearly seen and appeared to be partly destroyed. In the lateral view there was a slight deformity—suggesting erosion—of the posterior border of the body of the second lumbar vertebra. A puncture at the third lumbar vertebra produced slightly hemorrhagic xanthochromic fluid, which clotted on standing. There was no rise in pressure on jugular compression. The total protein of the fluid was 5880 mg. per 100 cc. Five tenths of a cubic centimeter of Pantopaque in oil was injected, and on lowering the head end of the table this was arrested opposite the upper margin of the third lumbar vertebra.

On the sixth hospital day an operation was performed.

A PHYSICIAN Was the tumor in the filum terminale?

DR. MIXTER It seemed to be. It was difficult to be sure whether it arose from a small nerve root or the filum terminale. The nerve roots were plastered on the outside and had to be dissected off. It was equally distributed on the two sides, behind and in front. The tumor did not look like a neurofibroma.

CLINICAL DIAGNOSIS

Tumor of cauda equina

DR. SEMMES'S DIAGNOSIS

Ependymoma of filum terminale

ANATOMICAL DIAGNOSIS

Ependymoma of filum terminale

PATHOLOGICAL DISCUSSION

DR. KUBIK The tumor was 5 cm long and about 11.5 cm in diameter. Histologically it chiefly consisted of small follicles of cells with well stained cytoplasm, in some places there were elongated cells whose bases rested against the adventitial connective tissue of the blood vessels. Our diagnosis was ependymoma. The appearance was suggestive of a slowly growing, relatively benign tumor. Some of the cases of ependymoma of the cauda equina that have been followed for several years have not demonstrated clinical signs of recurrence.

CASE 32492

PRESENTATION OF CASE

A fifty-one-year-old housewife entered the hospital because of pain in the left lower quadrant of the abdomen and vaginal discharge.

Eight months before admission an acute attack of sharp pain in the left lower quadrant occurred. Thereafter the attacks were often repeated, sometimes before and sometimes after the menstrual period. The pain was always in the same area. Usually the patient wanted to lie down during the attacks, but occasionally sitting up gave relief. Each bout lasted nearly an hour or less. During the two months preceding admission, following a trip to Ohio, there was a mucosanguineous vaginal discharge, which came on gradually and was continuous.

There had been hot flashes for three years, and catamenia dwindling from a regular period of five to three days over five years. An appendectomy had been performed eighteen years before admission. Two children were living and well.

Physical examination was negative except for the pelvis. There was a mucopurulent vaginal discharge. The perineum was markedly lacerated. There were a cystocele and a urethrocele. The cervix was large, with many nabothian cysts. A rough granular area was seen on the right posterior cervical lip. An irregular, hard, firm mass that was felt in the region of the fundus was three times the size of a

normal fundus and seemed to project more to the left than to the right.

Routine blood examination was normal. The urine gave a + test for albumin, and the sediment contained numerous white cells on the first examination but three days later contained 10 white cells and 15 red cells per high-power field. The guaiac reaction of the stool was negative. A vaginal smear was reported positive for tumor cells, but a second smear contained too much blood for satisfactory examination. Biopsy of several areas on the cervix, including the granular area, was reported as showing chronic endocervicitis.

An operation was performed on the fourth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. HOWARD ULFELDER This is the history of a fifty-one-year-old woman who was in the midst of the menopause, with hot flashes and some decrease in the length of the period, but still not missing a period, I gather. She had had two normal children. The only thing of interest in the past history is the fairly simple abdominal operation, which probably had nothing to do with the illness on admission. I take it that the patient had been well prior to eight months before admission, but that at that time she had an acute onset of pain in the left lower quadrant, which had recurred. I assume that there had been no associated gastrointestinal or urinary symptoms with these attacks. Their relation to the menstrual period must be considered, since they occurred both before and after the period. No mention is made whether they occurred during menstruation, however. In other words, they could have occurred at any time, so far as I can deduce from the record. They were well localized, always to the same area. They lasted for a variable period but never more than an hour, and there were no associated symptoms. Sometimes when lying down the patient felt more comfortable, but occasionally when sitting up she obtained relief. This means to me that it was not any one position that relieved the pain but rather a change of position that seemed to help. Although it is likely that the symptoms were associated with the pelvic mass, we must rule out extragenital sources for this picture.

Were intravenous pyelograms done? I wondered about that because of the few red cells and white cells in the sediment, and it is of interest, since these attacks of pain in the left lower quadrant could have been on the basis of genitourinary disease.

DR. TRACY B. MALLORY There was no pyelogram, and no barium enema.

DR. ULFELDER Assuming that we have more or less ruled out genitourinary causes of the symptoms, what could the diagnosis have been in a patient who had attacks of pain in the left lower quadrant, with some discharge that apparently was intermittently bloody, and who had a firm, hard pelvic mass, which felt like a fundus of three times the normal

suspicious of a tumor. Of course, this patient may have had some striking physical signs in favor of a ruptured disk, but in spite of this, with such a history, I think that this is a case in which a myelogram was indicated before operation. The record does not state whether a ruptured disk was found or removed.

It is significant that, following operation, the patient continued to have low-back pain on coughing and straining and that the leg pain was not relieved. That is not unheard of following removal of ruptured disks, but at the same time the patients usually obtain prompt relief.

Recovery from the paralysis of the bladder after a few weeks and improvement in the power of the legs are not incompatible with a tumor, since, paradoxically, periods of improvement are well known with tumors.

The constipation may have been the result of pain on straining, as in patients with cerebellar tumors, rather than paralysis of the colon.

It is to be remembered that this patient was explored on the left side for a ruptured disk in connection with the fact that the deep reflexes in the legs were lost, with the exception of the ankle jerk on the left.

Perhaps one should think of the possibility of a chronic osteomyelitis or an injury to the vessels, resulting in a false aneurysm or an arteriovenous fistula, since these accidents have been reported following operation for a ruptured lumbar disk. The later signs and symptoms, however, were at a higher level, and I think that they can be dismissed without further concern.

X-ray examination was reported to show erosion of the body of the second lumbar vertebra and the pedicles of the second and third. It would be helpful to know whether the bone destruction was caused by a malignant tumor involving the bone or by pressure atrophy such as that caused by large benign tumors in the central canal. On examining the x-ray films, it is evident that the bone changes were due to lateral pressure on the pedicles and forward pressure on the posterior surface of the second vertebra. The myelogram indicates an intradural, rather than extradural, tumor at the third lumbar level.

The spinal-puncture findings showed a complete fluid block, which was evidently of long standing, as indicated by the high total protein content. The presence of fresh blood in the spinal fluid suggests that the needle penetrated the lower end of the tumor or that there had been some sudden increase in pressure.

For a number of years, when encountering a fluid block, we have used injection of a few cubic centimeters of air (without a myelogram) and found that it is valuable in verifying the level by reproducing pain. In such cases the neurologic level is sufficient.

DR JAMES R. LINGLEY: These are the involved pedicles of the second and third lumbar vertebrae.

There is scoliosis, in spite of which there is evidence of thinning and erosion of the pedicles. In the lateral view the erosion on the posterior surface is not too well defined. In this film there is evidence of complete block at the upper level of the third vertebral body.

DR SEMMES: I believe that the patient had a long-standing tumor involving the cauda equina below and close to the conus, and that operation was certainly indicated. A variety of intradural tumors, including neurofibromas, ependymomas, meningiomas and gliomas, occur in this position. I was interested in knowing just where this one arose. The bilateral pain suggests that it was central, and the pain was certainly not like that from a neurofibroma involving an emerging nerve root, which would probably be attached to the filum terminale or one of the central filaments.

A PHYSICIAN: The neurologic level is much higher than the radiologic level. It seems to be somewhere around the upper part of the first lumbar vertebra. One might postulate that whatever the level was, a fairly long lesion was involved.

DR SEMMES: I am frequently content to know either the top or the bottom level of the tumor, preferably the latter, because it is easier to approach from below. It is unlikely that this was a round type of tumor, but one would expect a fairly long tumor—even longer than the neurologic changes suggested. I think that the pain at the costal margin was probably coincidental.

A PHYSICIAN: What would you say about the advisability of operating for herniated disk in a patient with bilateral pain and an atypical picture, without further investigation?

DR SEMMES: I tried to indicate that if a patient has a peculiar or atypical history, one should do a myelogram and consider the symptoms from various angles. In case of doubt, it is then a matter of exploration rather than operation for removal of a disk. I am not opposed to myelography, but I am opposed to unnecessary myelography.

DR CHARLES S. KUBIK: Dr. Mixter, do you wish to make any comments?

DR W. JASON MIXTER: It seemed to us when this case was presented at this hospital that it was a rather clear-cut case, as Dr. Semmes has suggested, of a tumor in the cauda equina, and that the previous operation might be criticized because it was done without a complete study. At operation the upper portion of the lumbar canal was exposed, presumably including the area of the twelfth thoracic vertebra, and a long slender tumor in the cauda equina, arising apparently from the filum terminale and doubling back on the conus, was exposed and removed.

DR KUBIK: What was the subsequent course?

DR MIXTER: The patient presumably made a fairly complete recovery. We were worried about the bladder, and I suppose that the reflex changes persisted.

THE CHRISTMAS SEAL CAMPAIGN

THE single flaw in the remarkable progress in the control of tuberculosis in the United States is the fact that the disease is still a major cause of death, killing more Americans than all other infectious and parasitic diseases combined. In spite of a constant search for drugs to effect a lasting cure, no substance has been found that is completely satisfactory. Thus, various sulfonamides, although capable of modifying the disease in experimental animals, have proved too toxic for continuous use in human patients, and streptomycin, which provides considerable protection, has not effected permanent cure. Since no specific remedy has been discovered, the accepted methods of treatment, which have obtained excellent results in a great many cases, must be relied on.

There can be no relaxation of effort until tuberculosis has been completely and permanently eradicated — a goal that at present appears possible only through continuous application of discoveries and advances already attained. Consolidation of the gains made and progress toward eventual eradication depend on a ceaseless campaign of case finding, rehabilitation and, most important of all, health education. In this program the annual sale of Christmas Seals, which supports the activities of the National Tuberculosis Association, is a vital part. The Christmas Seal Campaign not only enables the Association to continue and extend its efforts of prevention and control but also affords an ideal vehicle of health education — the Christmas Seal has become a familiar part of the pattern of American life, serving as a reminder that tuberculous infection is ever present, that no man is immune and that a great voluntary organization provides our primary bulwark against the spread of the disease. Americans in general recognize tuberculosis as an infection that under certain circumstances can be both prevented and cured and appreciate the necessity of early diagnosis.

This nationwide campaign epitomizes the best in the democratic way of life. Millions offer their contribution to the control of a dreaded disease and by this voluntary and concerted action gain protection from an enemy against which they are individually powerless. All lay and professional individuals and groups are urged to contribute as generously as possible. The medical profession, whose members are particularly aware of the vital implications of the Christmas Seal Campaign, should be in the vanguard of those offering support.

CLINTON'S NEW HOSPITAL

IT is with particular pleasure and satisfaction that we make mention of the ground-breaking ceremony, on October 16, for the new building of the Clinton Hospital. We congratulate Clinton on its new hospital-to-be, our special interest, however, lies in the fact that the ground was broken, physically and in person, by Dr. Walter Prentice Bowers, after whom this building will be named, who figuratively broke ground for the first Clinton Hospital, over

size? We cannot exclude cancer in a patient—not only of this age but also of any age—who has a bloody vaginal discharge, and I think that the diagnosis of either endocervical or uterine cancer must be entertained in this case. But if it was present I think that it was incidental rather than the basis for the symptoms, except perhaps for the discharge. I assume that this granular area on the cervical lip, where a biopsy had been reported as showing no evidence of cancer, explained the discharge. I cannot say that this woman did not have a cancer of the fundus or cervix, but if she did have cancer I do not believe that it explains all the symptoms. What then, in a woman of this age, is a mass, three times the size of a normal fundus, that is hard and firm? Statistically, it is a fibroid, which is more probable than ovarian tumor in this age group. On the other hand, even a pedunculated subserous fibroid would not cause the attacks of pain in the left lower quadrant of which this patient complained. I think that a solid tumor of the left ovary would be even harder and firmer than the one described. I therefore think that this is likelier to be a cystic tumor of the left ovary. The lack of endocrine effect—the patient had an uninterrupted progress of menopausal symptoms—suggests that this was not an endocrinologically functioning tumor and does not help in making the final diagnosis, it merely excludes a small group of possible pelvic tumors. My diagnoses are cystic tumor of the left ovary and possibly cancer of the endocervix or uterine fundus, which I cannot exclude or include on the basis of any information available. I shall not even discuss the smear.

DR. MARSHALL K. BARTLETT I should like to know how often positive vaginal smears are obtained in ovarian cancer.

DR. ULFELDER I cannot answer that because we have not correlated the ovarian lesion with smears, either positive or negative.

DR. BARTLETT We have seen some.

DR. ULFELDER Yes, but we have seen some either way. There is no relation suggesting that in the presence of ovarian tumor there is a distinguishable change in vaginal cytology. We have seen positive smears with ovarian cancer, but they were in cases in which the tumor had invaded the uterus, in direct continuity with the genital canal.

DR. CLAUDE E. WELCH How much significance does a positive smear have?

DR. ULFELDER Statistically, it is difficult to tell how significant it is. Certainly we can quote the findings and the figures in the presence of established cancer of either the cervix or the fundus. The smear fails to show evidence of cancer in 11.5 per cent. All I can say is that in our series, of a total of 2400 patients who did not have cancer that could be proved pathologically, 49 had positive smears. We went back over the 49 cases, and there were 30 that would not now be called positive

smears. They represent the error in learning a new method. But 19 of the patients had positive smears, which we were unable to confirm pathologically.

DR. MALLORY Speaking from the point of view of the pathologist, in cases in which we receive only a biopsy from either the cervix or the endometrium, there is always a possibility that the biopsy was not taken from the right place, and that may be one reason that we have failed to confirm some of the smear diagnoses. There have been a certain number of cases in which we have had the entire uterus to examine and in which, on routine examination, we have not found carcinoma. There is always, however, the possibility of a minute lesion, which could easily be missed in ordinary routine examination.

DR. WELCH I think that Dr. Ulfelder should be congratulated on his diagnosis. Examination under ether revealed the mass described in the record. The uterine canal was approximately 12 cm deep. Curettings were grossly normal. I assumed that we were dealing with multiple fibroids and that the mass in the left vault was a subserous leiomyoma. On opening the abdominal cavity it was obvious that there was a cystic tumor of the left ovary. On the uterus there were tiny fibroids that were not significant. There was no gross evidence of cancer.

CLINICAL DIAGNOSES

Leiomyoma

Rectocele

Cystocele

Lacerated hypertrophied cervix, with marked endocervicitis

Carcinoma of cervix?

DR. ULFELDER'S DIAGNOSIS

Cystic tumor of left ovary

Cancer of cervix or uterine fundus?

ANATOMICAL DIAGNOSES

Cystadenocarcinoma of left ovary

Leiomyomas of uterus, small

PATHOLOGICAL DISCUSSION

DR. MALLORY When the cyst of the ovary was opened it was found to be lined with innumerable papillary projections. We know that papillary cystic tumors of the ovary are at least potentially malignant. The epithelial cells in this tumor showed evidence of rapid growth and considerable irregularity of staining, and we called it a cystadenocarcinoma. In the other ovary a functioning corpus luteum was found, and the endometrium showed an early secretory stage. There was a moderate amount of functioning ovarian tissue, in spite of the preliminary symptoms of the menopause. We were unable to find evidence of cancer of either the cervix or the fundus of the uterus.

CLINTON'S NEW HOSPITAL

IT is with particular pleasure and satisfaction that we make mention of the ground-breaking ceremony, on October 16, for the new building of the Clinton Hospital. We congratulate Clinton on its new hospital-to-be, our special interest, however, lies in the fact that the ground was broken, physically and in person, by Dr. Walter Prentice Bowers, after whom this building will be named, who figuratively broke ground for the first Clinton Hospital, over

fifty years ago, and has been to a large degree its guardian since that time

We know Dr Bowers as a former president of the Massachusetts Medical Society, as the secretary for years of the Massachusetts Board of Registration in Medicine, as the managing editor of the *Journal* from 1921 to 1936, but particularly as a physician and friend, loved and respected. Clinton knows him for all this and as the physician who settled in that town over sixty years ago to spend there the most productive years of a long and industrious life in the practice of medicine and in the service of the community. We can all take vicarious pride in the fact that it was as a general practitioner that Dr Bowers received from Harvard University in 1935 the degree of Master of Arts, *honoris causa*.

It is fitting that Clinton's new and modern general hospital should be named after Clinton's foremost physician, for it can thus also stand as a memorial to the spirit of all general practitioners and to the leadership that they have so often given to their various communities. The practice of medicine will change and go forward, and more complicated technics will be developed, but the real value and the true function of the general practitioner will remain indispensable and indisputable.

MASSACHUSETTS MEDICAL SOCIETY

BUREAU OF CLINICAL INFORMATION

All secretaries of various medical groups, such as special societies and alumni associations, are requested to notify the Bureau of Clinical Information regarding scheduled meetings, annual dinners and so forth. If such data are on file, it is hoped that duplication of dates can be avoided.

DEATHS

DENNETT—Alonzo G. Dennett, M.D., of Lowell, died October 11. He was in his ninety-second year. Dr. Dennett received his degree from Rush Medical College in 1883.

His widow and a daughter survive.

McNAMARA—John J. McNamara, M.D., of Lowell, died November 13. He was in his fifty-second year. Dr. McNamara received his degree from Tufts College Medical School in 1923. He was a fellow of the American Medical Association.

His widow and two sons survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

COMMUNICABLE DISEASES IN MASSACHUSETTS FOR OCTOBER, 1946

RÉSUMÉ

DISEASES	OCTOBER 1946	OCTOBER 1945	SEVEN-YEAR MEDIAN
Anterior poliomyelitis	129	134	46
Chancroid	2	1	2
Chicken pox	478	331	370

*Made reportable December 1943

†Four-year average

COMMENT

Diseases reported at an incidence above the seven-year median included anterior poliomyelitis, chicken pox, diphtheria, German measles, measles and Salmonella infections.

Diphtheria showed the highest prevalence of any month since 1933 and had an incidence of more than five times that of October, 1945.

Diseases reported below the seven-year median included bacillary dysentery, meningococcal meningitis, mumps and scarlet fever.

Lobar pneumonia had an incidence that was only half that of the seven-year median and that comprises a record low for the month of October.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from Arlington, 3; Boston, 8; Blackstone, 2; Brockton, 1; Brookfield, 1; Brookline, 1; Cambridge, 1; Canton, 1; Chelsea, 1; Dracut, 2; Easthampton, 3; Essex, 1; Everett, 2; Fitchburg, 1; Framingham, 2; Franklin, 2; Gardner, 1; Groton, 1; Haverhill, 2; Hopkinton, 1; Holyoke, 1; Lakeville, 1; Leominster, 1; Lowell, 7; Lynn, 1; Malden, 4; Marlboro, 1; Medford, 3; Milford, 1; Milton, 1; Needham, 4; New Bedford, 1; Newton, 10; North Adams, 1; Quincy, 1; Revere, 1; Salem, 1; Scituate, 2; Shelburne, 1; Shrewsbury, 1; Somerville, 2; Southbridge, 3; South Hadley, 1; Stoughton, 2; Walpole, 1; Ware, 2; Wareham, 1; Watertown, 1; Webster, 1; Weston, 1; Winchendon, 1; Worcester, 32; total, 129.

Diphtheria was reported from Arlington, 1; Boston, 21; Brockton, 3; Cambridge, 2; Chelsea, 3; Dartmouth, 1; Everett, 1; Lowell, 3; Lynn, 3; Mansfield, 1; New Bedford, 2; Somerville, 46; Waltham, 1; Worcester, 1; total, 89.

Dysentery, bacillary, was reported from Boston, 1; Lexington (Metropolitan State Hospital), 4; Wrentham (State School), 1; total, 6.

Malaria was reported from Abington, 1; Boston, 5; Dedham, 1; Framingham, 1; Greenfield, 1; New Bedford, 1; North Andover, 3; Saugus, 1; Southboro, 1; Stow, 1; Wellesley, 1; Worcester, 3; total, 20.

Meningitis, meningococcal, was reported from Norwood, 1; Palmer, 1; Salem, 1; Somerville, 1; Springfield, 1; Waltham, 1; total, 6.

Meningitis, Pfeiffer bacillus, was reported from Malden, 1; total, 1.

Meningitis, pneumococcal, was reported from Lunenburg, 1; Marblehead, 1; total, 2.

Meningitis, other forms, was reported from Boston, 1; total, 1.

Meningitis, undetermined, was reported from Hanson, 1, Medford, 1, Norwood, 1, Uxbridge 1, total, 4
 Pottacosis was reported from Cambridge, 1, total, 1
 Salmonella infections were reported from Belmont, 2, Haverhill, 1, Hatfield, 1, Lawrence, 1, Lynn, 2, Peabody, 1, Swampscott, 2, total, 10
 Septic sore throat was reported from Amesbury, 2, Boston, 10, Brookline, 1, Cambridge, 2, Somerville, 1, Williamstown, 6, total, 22
 Tetanus was reported from Ashburnham, 1, Burlington, 1, Fall River, 1, total, 3
 Trichinosis was reported from Boston, 1, Fall River, 1, Mansfield, 1, Medford, 1, total, 4
 Typhoid fever was reported from Boston, 1, North Adams, 1, Wellesey, 1, total, 3
 Typhus fever was reported from Boston, 1, total, 1
 Undulant fever was reported from Bridgewater, 1, Maynard, 1, Millville, 1, total, 3

MISCELLANY

NATIONAL EMERGENCY MEDICAL SERVICE

Edward L. Bortz, M.D., of Philadelphia, chairman of the Committee on National Emergency Medical Service of the American Medical Association, recently announced the mailing of a comprehensive questionnaire to more than 45,000 discharged medical officers of World War II. "Since the results of the questionnaire will serve as a useful guide in preparing for any new national emergency," Dr. Bortz said, "the committee urges all the returning medical officers to express frankly, fully and completely their reaction to military service." The questionnaires were mailed from the headquarters of the American Medical Association during November and should be returned within a month after receipt. The results will be tabulated and analyzed in detail.

Dr. Bortz said that the committee believes that its final analysis and recommendations should cover not only the military services but also other governmental agencies, industry, medical education, research and civilian medical care.

The committee, in so far as possible, has provided check lists in this questionnaire. This makes it possible for the doctor merely to check the proper item and avoid taking the time to write out his answers. Some of the questions, however, will require written explanations. For example: "What important features of training were not sufficiently stressed? What in your opinion should be included in an ideal training program? If there was waste of personnel in your unit, please state how personnel could have been used effectively. What suggestions have you about methods of assignment of medical officers in the event of another military emergency?"

In discussing the questionnaire, Dr. Bortz stressed the desirability of deliberation on the part of every physician in answering the questions. "The objective sought," he said, "can be best attained by careful consideration of each and every question."

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

A Bibliography of Visual Literature 1939-1944. Compiled by John F. Fulton, M.D., Phebe M. Hoff and Henrietta T. Perkins. Publication No. 11, Historical Library, Yale Medical Library. Prepared by the Committee on Aviation Medicine, Division of Medical Sciences, National Research Council, acting for the Committee on Medical Research Office of Scientific Research and Development, Washington, D.C. 4° cloth, 117 pp. Menasha, Wisconsin. Printed by George Banta Publishing Company, 1945. \$3.00, postpaid.

This bibliography was primarily compiled for military purposes, and therefore a large amount of biochemical material on the aqueous and vitreous humors of the eye was arbitrarily omitted. The special literature on the lens was

also omitted because it is thoroughly covered for the war period in another work. In the section on therapy emphasis is placed on the newer developments both in surgery and chemotherapeutics. Special sections are devoted to the sulfonamides and to penicillin. Trachoma is included because of its importance as a military problem in certain war theaters. Three thousand, three hundred and forty-seven references are cited, and there are indexes of periodicals, authors' names and subjects. This bibliography should be in all medical reference collections, public-health libraries and the libraries of ophthalmologists.

Clinical Parasitology. By Charles F. Craig, M.D., M.A. (hon.), and Ernest C. Faust, M.A., Ph.D., professor of parasitology, Department of Tropical Medicine, Tulane University of Louisiana, New Orleans, consultant to the Secretary of War, Army Epidemiologic Board on Epidemic and Tropical Diseases, consultant, United States Public Health Service, and honorary consultant, Army Medical Library. Fourth edition, thoroughly revised. 8°, cloth, 871 pp., with 305 illustrations and 4 colored plates. Philadelphia: Lea and Febiger, 1945. \$10.00.

The authors in this fourth edition of an authoritative work have completely revised the text and under each important parasite have added a separate topic on pathogenesis. A new chapter has been added on the geographic distribution of parasitic infection. Much new information on preventive techniques has been incorporated throughout the text. A bibliography of thirty-nine pages and indexes of authors and subjects conclude the volume. This work should be in all medical reference collections, public-health libraries and the libraries of physicians interested in tropical diseases.

Fractures of the Jaws. By Robert H. Ivy, M.D., D.D.S., professor of plastic surgery, School of Medicine and Graduate School of Medicine, and of clinical maxillofacial surgery, School of Dentistry, University of Pennsylvania, chief of plastic surgery, Graduate Hospital, consultant in plastic surgery, Children's Hospital, and plastic surgeon, Presbyterian Hospital, Philadelphia, and Lawrence Curtiss, M.D., D.D.S., associate professor of plastic surgery, Graduate School of Medicine, assistant professor of maxillofacial surgery, School of Dentistry, University of Pennsylvania, chief of oral and plastic surgery, Bryn Mawr Hospital, associate in plastic surgery, Presbyterian Hospital, and consultant in plastic surgery, Delaware County Hospital. Third edition, thoroughly revised. 8°, cloth, 174 pp., with 199 illustrations. Philadelphia: Lea and Febiger, 1945. \$4.50.

In this new edition of a popular work a few changes have been made, but the general character of the text remains the same. Several new methods of treatment of fracture of the jaw have been described, and a number of new illustrations have been added to the text.

Acute Injuries of the Head: Their diagnosis, treatment, complications and sequelae. By G. F. Rowbotham, B.Sc. (Manch.), F.R.C.S. (Eng.), surgeon in charge, Department of Neurological Surgery, Newcastle General Hospital, neurologic surgeon, Royal Victoria Infirmary, Newcastle-on-Tyne, and Sunderland Royal Infirmary, and consulting neurologic surgeon, Durham County Council, Northumberland County Council, Sunderland Corporation and Gateshead Corporation. With a foreword by Norman M. Dott, M.B., Ch.B. (Ed.), F.R.C.S. (Ed.), lecturer in neurologic surgery, University of Edinburgh, neurologic surgeon, Royal Infirmary, Edinburgh, and Jordanburn Nerve Hospital, Edinburgh, honorary consultant in neurologic surgery to the Army in Scotland, and director in neurology and neurologic surgery, Brain Injuries Unit, Bangour E.M.S. Hospital, near Edinburgh. 8°, cloth, 424 pp., with 201 illustrations. Baltimore: The Williams and Wilkins Company, 1945. \$8.50.

This second edition has been revised in the light of knowledge gained from autopsies and clinical experience since the publication of the first edition in 1942. Two chapters on the theory of injury to the brain by the force of rotation and on rehabilitation, as well as new illustrations, have been added to the text.

Hey Groves' Synopsis of Surgery Edited by Cecil P G Wakeley, C.B., D.Sc., F.R.C.S., F.R.S.E., fellow of King's College, London, senior surgeon to King's College Hospital, director of surgical studies and teacher of operative surgery, King's College Hospital Medical School, surgeon, Belgrave Hospital for Children, West End Hospital for Nervous Diseases and Royal Masonic Hospital, consulting surgeon, Maudsley Hospital and Royal Navy, Hunterian professor, Royal College of Surgeons of England, and examiner in surgery, universities of Bristol, Cambridge, Durham and Sheffield. Twelfth edition. 12°, cloth, 632 pp. Baltimore: The Williams and Wilkins Company, 1945. \$6.00.

During the revision of this well known manual, Dr Groves died, and the work was completed by Dr Wakeley. The complete text has been carefully revised and brought up to date. Information on penicillin and the sulfonamides and on modern methods of radium therapy have been incorporated in the text. Some of the older amputations no longer in use have been omitted. This work was first published in 1908, and new editions have been necessitated every few years, speaking well for the popularity of the manual.

The Road to Recovery from Illness. A study of convalescent homes serving New York City. Prepared by Elizabeth G Gardiner and Francisca K Thomas for the Committee on Convalescent Care Practice. 8°, paper, 197 pp. New York: Hospital Council of Greater New York, 1945.

This report embodies the results of a study made on convalescent care in 1941 and 1942 by a special committee representing various New York hospitals and welfare organizations. A survey of the convalescent homes in the New York City area was made by field representatives working for the committee. The study covered the various social and medical aspects of the problem. As a result of the findings, the committee made extensive recommendations concerning co-operation of all agencies in the area, as well as convalescent homes. One of the principal recommendations was that a department of convalescent care be created as a central agency and that all homes serving the population in New York City, regardless of geographical location, should be integrated by this central agency into a community plan for organized medical care. The recommendations for the homes covered medical supervision and health, personnel, policies and plant. The report concludes with various recommendations for the referring agencies.

Diseases of the Nose, Throat, and Ear, including Bronchoscopy and Esophagoscopy. Edited by Chevalier Jackson, M.D., Sc.D., LL.D., and Chevalier L. Jackson, M.D., M.Sc., professor of bronchoesophagology, Temple University, Philadelphia. With the collaboration of sixty-four outstanding authorities. 4°, cloth, 844 pp., with 934 illustrations. Philadelphia: W. B. Saunders Company, 1945. \$10.00.

This new textbook is the combined effort of a large number of contributors with extensive clinical and teaching experience who are also thoroughly acquainted with the literature of their respective subjects. Of special interest are the articles on endoscopic photography, aviation otolaryngology and chemotherapy.

NOTICES

ANNOUNCEMENTS

Dr Howard Hoffman announces the opening of his office for the practice of urology at 422 Beacon Street, Boston.

Dr David Karp has returned from military service and has resumed the practice of pediatrics at the Medical Building, 59 Coddington Street, Quincy.

Dr K. W. Thompson, formerly of 1101 Beacon Street, Brookline, announces that he has retired from the practice of surgery and has been appointed medical director of Roche Organon, Incorporated, Nutley, New Jersey.

Dr Merrill L. Welcker announces the opening of his office in the Medical Arts Building, Suite 311, 36 Pleasant Street, Worcester, for the practice of internal medicine.

NAVAL RESERVE OFFICERS

The attention of reserve medical officers of the United States Navy is invited to the opportunity to perform full-time active duty at one of the major naval air stations of the Naval Air Reserve Training Command or at one of the Naval Air Reserve Training Units.

Officers in the above category who are interested in full-time active duty as a member of the stationkeeper staff at one of these stations or units should initiate letters to the Bureau of Naval Personnel, via the Chief of Naval Air Reserve Training, Naval Air Station, Glenview, Illinois, listing three or four stations at which duty is desired in order of preference. Personnel are desired in the ranks of commander and lieutenant commander.

Officers qualifying for the above billets can be assured of every consideration in obtaining and continuing duty at the station of their preference. It is the policy of the Command to obtain "orders to duty involving flying" for designated naval flight surgeons. Government quarters are available at many of the major naval air stations.

Reserve naval flight surgeons who are desirous of affiliating themselves on a part-time basis with either the organized or the volunteer components of the Inactive Reserve, composed of air groups training at one of the Naval Air Stations or Naval Air Reserve Training Units should contact the Commanding Officer of the station or the unit at which the training group is based.

AMERICAN COLLEGE OF SURGEONS

The five-day Clinical Congress of the American College of Surgeons will open in Cleveland on Monday morning, December 16, at 9:30 o'clock. This will be the first annual meeting of the College since 1941. Headquarters will be in the Cleveland Public Auditorium and the Statler and Cleveland hotels, with most of the sessions, except the clinics at the hospitals, being held in the auditorium. The program will include operative and nonoperative clinics, demonstrations, symposiums, panel discussions, forums, medical motion pictures, exhibits, and the twenty-fifth Annual Hospital Standardization Conference, which will convene during the first four days.

BOSTON MEDICAL HISTORY CLUB

There will be a meeting of the Boston Medical History Club in Sprague Hall at the Boston Medical Library, 8 Fenway, on Monday, December 9, at 8:15 p.m. Mr. James F. Ballard will speak on "Bibliography, Past and Present."

All interested persons are cordially invited to attend this meeting.

NEW ENGLAND HEART ASSOCIATION

A meeting of the New England Heart Association will be held at the Peter Bent Brigham Hospital on Monday, December 16, at 8:15 p.m.

PROGRAM

Some Auscultatory Phenomena Illustrated by Phonocardiograms. Drs. Proctor Harvey and Samuel A. Levine.
Circulatory Changes in Experimental Pulmonary Embolism. Drs. Lewis Dexter, Thomas D. Kinney and Florence W. Haynes.

Circulatory Dynamics in Bern-beri Heart Disease. Drs. C. Sidney Burwell and Lewis Dexter.

Vascular Anomalies Producing Esophageal or Tracheal Compression. Dr. Robert E. Gross.

The Clinical Features of Patent Ductus Arteriosus. Dr. Samuel A. Levine.

Interested physicians and medical students are cordially invited to attend.

SOUTH END MEDICAL CLUB

The next regular meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, December 17, at twelve noon. Dr. John J. Curry will speak on the topic "Recent Advances in Therapy with Drugs Affecting the Autonomic Nervous System." Dr. C. A. Pattajyo will preside.

Physicians are cordially invited to attend.

TRICHINOSIS

A Review of Cases in Massachusetts from 1936 to 1945

ROBERT E. OBER, M.D.*

QUINCY, MASSACHUSETTS

FOR many years, concerted attempts have been made through the press, magazine articles, popular pamphlets and other channels to impress on the public the danger of contracting trichinosis. Such catch phrases as "Perils of pink pork"¹ and "Why don't we trim trichinosis?"² have been useful in attracting the attention of the general public to the dangers inherent in insufficiently cooked pork. Recently, the death of a Massachusetts physician from a proved trichinella infection indicates that it is difficult even for a highly trained person to recognize improperly cooked pork. Undoubtedly, much pork is consumed daily that harbors trichinae. Nor can it be denied that many cases of human infection are not recognized by the patient or the physician. Hall and Collins,³ in 1937, and Nolan and Bozicevich,⁴ in 1938, routinely examined the diaphragms at autopsy of 1000 consecutive patients in whom the diagnosis of trichinosis had not been considered clinically. They found *Trichinella spiralis* in 174 cases—an incidence of 17.4 per cent. Numerous other investigators have made similar studies of autopsy material in various parts of the country and reported varying results.⁵⁻⁸ Evans⁹ observed *T. spiralis* in 36 per cent of 100 post-mortem cases. There can be no question, therefore, that human infection with trichinae is a relatively frequent condition, probably being present in about 15 per cent of all cases at autopsy.

In Massachusetts, although trichinosis is not reported with great frequency, it cannot be considered a rare disease. In the ten-year period 1936-1945, a total of 287 cases were reported to the Massachusetts Department of Public Health, with death in 7 cases, a mortality of 2 per cent (Table 1). No particular section of the Commonwealth appears to be either immune or subject to an unduly high incidence of the disease, cases have been reported with regularity from all areas (Fig. 1). A total of eighty-one different communities reported one or more cases during this ten-year period. Owing to many factors, however, there can be little doubt

that many more patients were so mildly ill as never to come under medical care. Attention is usually directed to cases occurring in groups or in so-called "epidemic" form, single cases may escape detection.

EPIDEMIOLOGY

Trichinosis is caused by a small parasitic nematode—*T. spiralis*—that was first recognized in 1835 by Owen. Encysted forms of larvae present in infested pork are ordinarily responsible for the origin of the human infection. Human gastric juices destroy the encysting capsule, freeing the contained worms, which then pass on into the duodenum.

TABLE 1 Statistics in Cases of Trichinosis in Massachusetts

YEAR	No. of CASES	No. of DEATHS
1936	36	2
1937	21	1
1938	29	1
1939	14	1
1940	46	2
1941	50	0

and jejunum and mature into adult male and female forms. Copulation ensues, the male worms die and the females bore into the intestinal villi to reach the lymph spaces, where their eggs are deposited. These rapidly hatch to the larval stage and are carried via the thoracic duct to the lung capillaries and heart. The larvae are then disseminated from the heart into the peripheral arterial system and reach the distal capillaries. Sites especially prone to involvement with larvae are the eyelids, diaphragm and striated muscles, especially the gastrocnemius and deltoid. Active migration of the larvae occurs as they pass from the blood vessels and penetrate into muscle fibers. If a larva fails to penetrate a striated muscle fiber, it is

(Notices continued on page xix)

per cent) involved groups of 2 to 8 people in a total of thirteen separate outbreaks. Pork ingestion was readily traceable in all but 4 cases, the majority of patients admitting frequent exposure to pork meat. In 11 cases there were notations that the pork had been eaten raw—usually because the woman of the household had sampled pork-sausage meat to ascertain its spiciness. Members of the same households who had eaten the cooked product suffered no ill effects. This may possibly account for the fact that 47 of the 70 cases, or 67 per cent, occurred in women. The ages ranged from five to eighty-eight years.

The incubation period was difficult to ascertain in most cases owing to the frequency of pork ingestion. In retrospect, however, 26 cases showed nausea, vomiting, diarrhea and abdominal cramps early in the illness, and a history of pork ingestion within three to five days could be obtained. Most cases, however, showed only symptoms referable to the stage of larval dissemination. There was also difficulty in determining the time lapse, but in 9 cases it was believed with relative certainty that such symptomatology occurred from ten to fourteen days after the ingestion of pork. These figures agree with what may reasonably be anticipated from a knowledge of the life cycle of the trichinae.

During the dissemination stage, the peripheral signs and symptoms were recognized (Table 2)

TABLE 2 Clinical Signs and Symptoms in Disseminative Stage of Trichinosis

Sign or Symptom	No. of Cases
Temperature elevation*	67
Malaise	52
Edema of eyelids	47
Conjunctival involvement	10
Facial edema	19
Muscle pains	
Generalized	27
In legs	15
In upper extremities	2
In neck	2
In back	4

*Includes temperatures of 99 to 105°F, with an average of 101.3°F

Edema of the eyelids was a predominant feature in 47 cases, or 67 per cent. Conjunctival involvement included either edema or hemorrhage into the conjunctiva, or was recorded as "conjunctivitis." Only 1 case occurred in which concomitant edema of the eyelids did not exist. Facial edema was prominent in 19 cases, but in only 2 was edema of the eyelids absent. Muscle pains were relatively prevalent, being prominent in a total of 51 cases (71 per cent). Generalized muscular pains were prominent in 27 cases, or 39 per cent. The legs were specifically mentioned in 15 cases, with frequent notations specifying the gastrocnemius muscles or calves in contradistinction to the upper extremities, in which the arms and shoulders were both mentioned as the sites of discomfort.

Less frequent findings were those indicating pulmonary involvement, chest consolidation being reported in 1 case, chest pains in 4 and cough in 3. Cervical adenitis was mentioned once, as was splenomegaly. Abdominal distention and edema of the extremities were each described twice. Blurring of vision, profuse perspiration and skin rash were described in 4 cases, the last being generalized in 2 and confined to the chest in 1 and to the lower extremities in 1.

Laboratory examinations included white-cell counts, differential counts for eosinophils, precipitin tests, skin tests and muscle biopsies. White-cell counts were reported from 5000 to 26,000, with an overall average of 14,500 and individual cases showing fluctuations from 5000 to 19,000. Eosinophilia was characterized as "elevated" in 16 cases, whereas in the remainder the eosinophil count was specifically recorded in figures ranging from 6 to 85 per cent, individual cases showed fluctuations of as much as 55 per cent on repeated counts. The count was 32.5 per cent as an overall average and was 10 per cent or less in only 5 cases.

Precipitin tests were reported in a total of 16 cases, of which 13 were positive. Skin tests were done in 15 cases, with positive readings in 9. Most of the negative readings, however, were single tests, all done within four or five days of the onset of the symptoms. Undoubtedly, repeated tests would have resulted in a greater number of positive readings.

Muscle biopsy, which was made in 7 cases, was reported negative in 3, positive in 3 and as showing "interstitial myositis" in 1.

The establishment of the diagnosis of trichinosis is ordinarily done in the stage of larval dissemination. Fever, malaise, muscular pain and edema of the orbital region are the most frequent and significant findings. Eosinophilia, often of a high degree, points to the diagnosis. Precipitin and skin tests, together with muscle biopsy, offer a positive diagnosis but are subject to certain limitations and interpretations.

A definite diagnosis is rarely made in the early stages. Reported earlier diagnoses in the 70 cases described above had included "grippe," acute nephritis, chronic rheumatic fever, pyelonephritis, gastroenteritis, staphylococcal infection, food poisoning and poliomyelitis. Pepper³⁸ mentions typhoid fever, angioneurotic edema, meningitis, tetanus and acute sinusitis as being possibilities in differential diagnosis.

PREVENTION

Since the therapy of trichinosis has not been highly satisfactory,³⁷ the main interest revolves about the prevention of the disease. Inspection of meat by federal agents does not mean that any meat or meat product can be guaranteed to be free of trichinae. Because of the technical difficulties involved, meat cannot be investigated for *T. spiralis*.

quickly surrounded by a focus of acute inflammatory exudate and destroyed. Since the adult worms in the intestines live about four or five weeks, they may produce larvae for a prolonged period. With death, the adult worms are discharged in the feces. Larvae that reach a locus within a muscle fiber grow somewhat in length, assume a spiral form and become encysted, remaining alive and capable of development for many years. Many such cysts become calcified, and the contained larvae tend to die after a number of years.¹⁰

Porcine infestations undergo the same course. Rats have also been mentioned frequently as sources of *T. spiralis*, although their exact role in the transmission seems to be somewhat obscure.¹¹ Those who

and are followed by a period of muscular aching, pain and tenderness, chills, a temperature up to 105° F, cough, edema of the eyelids and skin rash. Not infrequently, signs and symptoms of pulmonary,¹⁹ cardiac²⁰⁻²² and central-nervous-system²⁴⁻²⁸ involvement are found. Undoubtedly, Augustine's¹³ observations that the inflammatory exudate surrounding the larvae reaching the brain, heart and pancreas destroys the parasites explains why such involvement is only transient. A similar action, he believes, accounts for the inability of the trichinae to pass across the placenta and involve the fetus in utero.

The period of peripheral symptomatology lasts as long as the adult worm is producing eggs—five to seven weeks. Death of patients affected occurs most frequently from the third to the sixth week. Although recovery is usually complete, vague rheumatic pains may persist for about a year.¹⁵

LABORATORY FINDINGS

The most frequent laboratory aid is the eosinophil count. Trichinosis almost invariably causes a relative and absolute eosinophilia. This fact, which has long been recognized as one of the most reliable signs of trichinosis,²⁹⁻³² is not in itself diagnostic but merely presumptive, other laboratory tests being necessary for absolute diagnosis.

The precipitin test, which is usually done by the National Institute of Health at Bethesda, Maryland, is highly sensitive. Unfortunately, it has several drawbacks. Early in the illness it may be negative, three or four weeks often being required before the precipitin titer is elevated. Repeated tests, however, showing a rising titer during the illness as well as the convalescence, are diagnostic.³³ This high titer may persist for years, thus obscuring the diagnosis of some other unrelated illness.³⁴

The skin test is of value if there is first an initial negative response to intradermal injection of the antigen, followed at a later date by a positive reaction, or if a delayed positive reaction is followed by an immediate positive one.³⁴ Immediate positive skin tests may represent an infection with *T. spiralis* as long as three years previously.³⁵

Muscle biopsy, if positive, makes diagnosis certain, but is often objectionable to the patient, takes time and frequently yields negative results.

Dammin³⁴ suggests utilizing the technic of Herick and Janeway³⁶ for the demonstration of larvae in the arterial blood. Although this procedure seems to offer a positive diagnostic aid, other references to its use have not appeared in the recent literature.³⁷

CASES IN MASSACHUSETTS

A review of the 287 reported cases of trichinosis in Massachusetts reveals 70 in which sufficient information was available to the Department of Public Health for evaluation of epidemiologic, clinical and laboratory data. Of these, 39 (approximately 55

FIGURE 1 Massachusetts Communities Reporting Trichinosis during 1936-1945

have watched rats feeding in the troughs from which swine are fed can readily realize their importance in this respect. In addition, *T. spiralis* has been described in foxes, badgers, martins, raccoons and so forth,¹² although no epidemiologic significance can be ascribed to this observation. Undoubtedly, the porcine reservoir is the basis for the organism found in rats, swine and human beings. Infested meat scraps fed to pigs in the form of garbage are undoubtedly the chief sources of porcine and rodent infestation.¹⁸ Unusual sources, such as that traced to bear meat by Westphal,¹⁴ play a relatively small part.

SYMPTOMATOLOGY

During the course of the life cycle of *T. spiralis* in human beings, certain signs and symptoms become manifest with each phase of larval development. Ordinarily, cases of great clinical severity can be attributed to an initial ingestion of large numbers of trichinella cysts with their subsequent development.¹⁶ The first symptoms are generally gastrointestinal, consisting of nausea, vomiting, abdominal pain and diarrhea. Recurrent infections may result in immunity to the adult worms and in their elimination from the intestinal tract by active diarrhea shortly after ingestion, as the investigations of McCoy^{16, 17} and Roth¹⁸ demonstrated in experimental studies on rats and guinea pigs. Gastrointestinal symptoms last three to five days

TROPICAL DISEASES IN VETERANS OF WORLD WAR II*

CAPTAIN JAMES J SAPERO (MC), U S N †

SINCE the cessation of hostilities, some ten million soldiers, sailors and marines have returned from overseas and resumed civilian life. Because a significant percentage served in areas notorious for the prevalence of tropical and exotic diseases, a serious concern quite justifiably exists regarding the possible effects on civilian public health and on civilian medical practice in general.

Butler and Saperó,¹ in 1945, analyzed the possibilities of new tropical diseases being introduced into the United States and stated that, during the two-year period 1943-1944, many thousands of servicemen who had acquired tropical diseases overseas had already returned and that no new foci of tropical disease had appeared in civilian communities in this country as a result. In spite of the great influx of patients suffering from recurrent malaria, the opinion was expressed that it was unlikely that carriers of this disease would cause a significant increase in the total incidence of malaria in the United States or that there would be an appreciable occurrence of malaria in areas previously free of the disease. The fact was emphasized, however, that the South Pacific strain of vivax malaria was more virulent and seriously disabling than any prevalent in this country. Concern was expressed that if this strain became established in the United States, it would greatly aggravate the malaria problem.

None of the other tropical diseases seemed to present any discernible hazard. Viewing the problem broadly, it was concluded that there appeared little cause for alarm regarding postwar morbidity from tropical diseases newly introduced into civilian communities.

It is now possible to review the estimate of the situation as it appeared in November, 1944, in the light of further experience. Since that time, several million members of the armed forces have returned to civilian life, and specific data on tropical diseases acquired by the armed forces during the entire war period have become available. Although the conclusions derived from the earlier analysis remain substantially the same, a clearer definition of the effects that tropical diseases may exert on postwar civilian life is now possible.

DISEASES OF MAJOR OCCURRENCE

Dysentery and diarrhea, malaria, infectious hepatitis and dengue, in respective order of frequency,

constituted the tropical diseases of major occurrence in some 11,300,000 persons who served overseas from 1942 to 1945, inclusive (Table I). As in almost every war in the past, the dysenteries, which occurred in approximately 6700 out of each 100,000 men, headed the list of the tropical diseases in World War II. Malaria, as might have been guessed, ranked second in frequency, with a rate of 5100 per

TABLE I Tropical Diseases in the Armed Forces, 1942-1945

100,000. A surprising finding, however, was the occurrence of infectious hepatitis as the third disease on the list, with an approximate rate of 1700 per 100,000. The fourth disease — dengue — had a rate of 1100 per 100,000.

Dengue

In evaluating the four diseases of most frequent occurrence in the light of their potential postwar effect on civilian life, it can be said that dengue at least presents no problem. There has been no case in which this disease, once widely prevalent in the United States, has been reintroduced, nor are there chronic sequelae that will require medical care during the postwar period.

Malaria

The status of malaria is more difficult to evaluate. It may be said, however, that the vast majority of malarial infections contracted during the war have run their course. Military hospitals, overcrowded in 1943 with cases of malaria, now are treating only an occasional patient for the disease. Fortunately, the syndrome of so-called "malaria cachexia" has occurred rarely, if at all, even in the more persistent

routinely or completely. Microscopic examination of pork is highly unreliable and is not utilized as a routine measure. It must also be realized that only 60 per cent of the hogs slaughtered in this country are federally inspected.³⁹ Attempts have been made by various state legislatures to compel hog breeders feeding garbage to hogs to steam cook all such material. Although this procedure undeniably destroys parasites present in pork scraps,⁴⁰ the time and expense involved do not make this practice popular. In Canada, however, where such cooking is governed by statute, the reported number of cases per 100,000 population is one twelfth that in the United States. Gould⁴¹ suggests a newer method of control that may eventually prove more acceptable. Freezing of pork at a temperature of 5°F for twenty days in sections 15 cm or less in thickness destroys trichinae. Raw pork kept at 0°F for seventy-two hours is rendered free of living parasites, and ground pork preserved at the same temperature is freed of *T. spiralis* in a few minutes. If this method is generally adopted and all pork refrigerated at the required temperatures, it is entirely conceivable that a generalized decrease in trichinosis can be anticipated. The growing popularity of deep-freeze cabinets in the home may be expected to contribute to this end.

Ultimately, however, the control of trichinosis is the responsibility of the consumer. Uncooked pork, regardless of the source and regardless of whether it has been inspected by federal, state or city authorities, must be considered unsafe unless properly cooked. Undoubtedly, much of this type of pork is perfectly safe, but the added factor of proper cooking is of sufficient value to be advised routinely. Ordinarily, the main sources of difficulty are not in eating the various pork products raw but in cooking them to an insufficient degree. Cooking must remove all traces of pink color from the meat and leave it a dull white. Then, and only then, can pork be considered noninfectious for *T. spiralis*.

SUMMARY

Of 287 cases of trichinosis reported in Massachusetts from 1936 to 1945, a total of 70 are reviewed for epidemiologic, clinical and laboratory data of significance and compared with the accepted clinical picture of the disease.

The clinical findings most frequently noted were fever, malaise, orbital edema and muscle pains. Eosinophilia was the most constant laboratory finding but must not be considered diagnostic in itself.

The control of trichinosis, in the final analysis, can be guaranteed only by the complete cooking of all pork and pork products. New deep-freezing methods may soon be expected to aid in the lowering of infectivity of pork.

had jaundice should be taken, and when the history is positive, special studies to reveal either latent or overt hepatic dysfunction should be made

DISEASES OF LESSER BUT SIGNIFICANT OCCURRENCE

Whereas Table 1 lists in the first group four diseases whose numerical occurrence was in the hundred thousands, the second group involved at the most less than one tenth as many patients

The reported occurrence of 20,000 cases of hookworm undoubtedly represents a small fraction of the actual number of patients who acquired this infection. Prewar Army and Navy surveys indicated an incidence of *Necator americanus* infections in from 5 to 10 per cent of recruits from the South. Postwar surveys of personnel who have served overseas show by comparison that a significant number of new infections have been acquired in endemic areas overseas. Fortunately, infections sufficiently heavy to cause serious clinical manifestations have not occurred frequently. In most of the hookworm-positive cases the infection is light, and the worms are lost spontaneously.

Whereas the over-all problem from a clinical standpoint appears of little importance, the fact that many of these men have acquired infections with *Ancylostoma duodenale* is a matter of some concern. *A. duodenale* is not at present found in the endemic hookworm areas of the United States. Thus, there is a possibility that returning servicemen, in unsanitated areas, will cause the introduction of this species, which is considered more pathogenic than *N. americanus*.

Careful studies by both the Army and the Navy now permit the statement that few, if any, permanent disabilities will result from filariasis. Furthermore, repeated blood studies have shown the occurrence of microfilaria to be exceedingly rare. Since transmission is dependent on their presence in the blood stream, this suggests that filariasis is unlikely to become established in the United States.

Neither endemic nor scrub typhus appears likely to present a postwar problem. Of the total of 893 cases of endemic typhus, practically all were actually acquired in the United States, this is in contrast to almost all the other diseases, in which the vast majority of cases were acquired overseas. Regarding cases of scrub typhus, most of which were acquired in the Southwest Pacific or in the China or India-Burma Theater, the absence of a suitable vector in the United States and of acute cases as sources of infection renders postwar dissemination improbable. For the same reason sandfly fever can likewise be said to have no particular postwar importance. It is believed that as a result of careful search among exposed groups practically all cases of schistosomiasis have been diagnosed and given intensive curative treatment.

The most serious disease in this group in all probability is amebic dysentery. It can be said with

certainty that the actual number of infections far exceeds those reported. The problem is not one of introduction or dissemination, for it is well known that the causative organism, *Endamoeba histolytica*, is already prevalent in 10 per cent of the population of the United States. The difficulties are clinical, being due to latency, chronicity and, most of all, the frequently obscure symptoms that mitigate the chances of recognition of amebic infections.

DISEASES RARELY ENCOUNTERED

In contrast to the first two groups of diseases, the third group in Table 1 has been compiled principally to show certain tropical diseases that, although they might have been expected to occur fairly often, were actually acquired rarely or not at all.

Of great interest is the fact that the wartime prevalence of the five quarantinable diseases—smallpox, cholera, plague, epidemic typhus and yellow fever—was insignificant when one realizes the large numbers of men and women operating in areas in which an appreciable hazard of acquiring these diseases existed.

Of importance, however, is the occurrence of 125 cases of smallpox. In every case in which full information was available, it was found that the fault lay in failure to obtain successful vaccination. There has not been a single case that would lead to suspicion that American-produced vaccine failed to protect even against the extremely virulent Oriental strains of smallpox.

Despite the relative rarity with which smallpox occurred, this disease has led to outbreaks in civilian communities as a result of introduction by members of the armed forces. Two localized epidemics have been reported. In San Francisco, 6 cases that appeared in civilians were assumed to be traceable to a case in a soldier who arrived in the acute stage of the disease from overseas by airplane. More serious is the recent epidemic in Seattle, in which up to the present, there have been some 59 cases, with 16 deaths, originally traceable to a soldier who arrived by surface vessel.

Even prior to the introduction of smallpox into these two civilian communities, its first occurrence in servicemen overseas was followed by an intensive program of revaccination of all exposed personnel in both the Army and Navy. Tightening of aircraft and ship quarantine, as a further safeguard, was instituted. Quarantine officers of the United States Public Health Service, working in close collaboration with quarantine officers of the armed forces, are maintaining close surveillance of all men returning from overseas to prevent, so far as possible, any further epidemics of quarantinable disease, such as those in San Francisco and Seattle.

The epidemics of smallpox on the West Coast forecast a potential hazard of considerable future public-health significance. Civilian air travel from

infections. Another point of practical postwar importance to physicians is that such cases of recurrent malaria as may be encountered will almost without exception be those of the benign tertian type. Quartan malaria, a disease that is apt to persist for many years, has been acquired only by an exceedingly small number of service personnel. Infections of malignant tertian malaria, although not of infrequent occurrence overseas, are of short duration, readily respond to treatment and, unlike benign tertian infections, do not tend to recur. As a result, malignant tertian infections have not been encountered in servicemen returning from overseas, except in the few who have come directly to this country after recent exposure in a malarious area.

In spite of previously expressed concern regarding the introduction of a new strain of malaria, no evidence has been forthcoming that the more seriously disabling South Pacific strain of *Plasmodium vivax* has become established in this country. It is not possible, however, to be at all certain on this point, since considerable time will elapse before its establishment is apt to be recognized. If establishment occurs, not only will cases infected with this exotic strain have a severer clinical course but also the relapses will be more frequent than those of the indigenous strain of benign tertian malaria. Of even greater import, the American Negro, although relatively refractory to the *P. vivax* strain in the United States, appears as susceptible as nonimmune Whites to the South Pacific strain. This means that the Negro population of the South may suffer serious consequences if the South Pacific strain becomes established in this country.

So far as it is known, there is only one report of a case in which malaria transmission appeared in the United States in an area previously free of the disease. In 1945 Osgood² described 2 primary cases of malaria in civilians in Oregon in an area where anophelines capable of transmitting the disease were found, and where a returned soldier was identified as a carrier and the probable source of the disease.

Although malaria in men returning from overseas is becoming relatively rare, and the peak of opportunity for introduction into new areas thus appears to have passed, it is of interest to note that Watson³ recently demonstrated that *Anopheles quadrimaculatus*, the important vector of malaria in the United States, is capable of transmitting the South Pacific strain of *P. vivax* malaria. Thus, a distinct hazard still exists and warrants maximal measures of anopheline control.

Bacillary Dysentery

Fortunately the vast majority of cases of bacillary dysentery and diarrhea encountered in the armed forces have been mild and of short duration. That chronic disabilities from dysentery are not likely

to present a major postwar problem is evident from the small number of patients with chronic dysentery now under treatment in military hospitals. Special epidemiologic reports on Navy personnel indicate that few persistent carriers have resulted from wartime-acquired dysentery. Although this suggests that overseas veterans as a group probably not present a particularly dangerous carrier problem, careful public-health scrutiny will be required to ascertain whether such a view proves to be true in practice.

Infectious Hepatitis

Of the four most frequent diseases, infectious hepatitis appears by far the likeliest to lead to significant postwar repercussions.

The total figure for the armed forces includes hepatitis transmitted in two distinct ways. One method of transmission resulted in epidemic outbreaks usually associated with a widespread prevalence of dysentery. The mechanism of transmission in these outbreaks, although not definitely established, is assumed to be similar to that in dysentery transmission. In addition, the figures include an indeterminate but significant number of cases of so-called "homologous serum jaundice." These cases followed the therapeutic use of blood or blood products unknowingly obtained from donors harboring the hepatitis virus. For example, of the total of 172,000 cases in the Army, a large number were jaundice infections that resulted from the program of yellow-fever vaccination, in which certain lots of vaccine, to which human serum had been added, were contaminated with the jaundice-producing virus. Other cases followed the use of whole blood or plasma obtained from donors who were probably experiencing unrecognized subclinical attacks. The injection of pooled lots of convalescent serum into a series of patients is especially hazardous. In this procedure, the chance of including a donor who may be carrying the virus is increased, and since there are multiple recipients, a large number of cases of hepatitis may follow.

The essential postwar danger to the civilian population is that the high wartime prevalence of hepatitis in the armed forces may lead to an increasing civilian prevalence by passage of the icterogenic virus in the therapeutic use of blood. Fortunately, there is already keen appreciation of this problem, and active research is underway to set up necessary safeguards. Until safe methods can be devised, physicians must recognize and evaluate the danger involved and weigh this danger in the individual case against the prospective therapeutic advantage.

Another point of practical significance in the large-scale occurrence of hepatitis in the armed forces is the fact that at least a small percentage of patients may develop cirrhosis. In the medical care of veterans, a careful history to determine if a patient has

TABLE 1 *Data in 10 Cases of Tetanus among German Prisoners*

Case No.	INJURY	INCUBATION PERIOD	SPECIFIC PROPHYLAXIS	OPERATIVE TREATMENT	ANTITOXIN THERAPY		CHEMOTHERAPY AFTER DIAGNOSIS	TRANSFUSION	COMPLICATIONS	RESULT
					INTRAVENOUS	INTRAMUSCULAR				
		days			A units	A units				
1	Gushot wound of right thigh and compound fracture of femur	6	None recorded	Redebridement	40 000	30 000	None recorded	500 cc of blood	None recorded	Death 24 hours after beginning of treatment
2	Penetrating wound of hand and compound fracture of metacarpal	8	1500 units of antitoxin 5 days after injury	Amputation of left hand above wrist	20 000	50 000	None recorded	None recorded	High temperature and severe spasms	Death
3	Severe burns of face, hand, thigh and knee	10	0.5 cc. of toxoid 1 day after injury	None	20 000	60 000	1 gm. of sulfadiazine every 4 hours and 20 000 units of penicillin every 3 hours	None recorded	Pulmonary atelectasis, pulmonary edema, pleural effusion and anemia (red cell count of 1,500 000)	Death on third day of treatment
4	Gushot wound of right forearm, compound fracture of right ulna, penetrating wound of chest and laceration of scalp	14	1500 units of antitoxin 8 days after injury	Amputation of right arm above elbow	40 000	100 000	23 gm. of sulfadiazine and 1 000 000 units of penicillin	750 cc of plasma and 2000 cc of blood	Atelectasis of right lung, fecal impaction and oliguria	Recovery
5*	Compound fracture of metacarpal and six other penetrating and lacerating wounds	22	1500 units of antitoxin on day of injury	Redebridement of all wounds	30 000	140 000	640 000 units of penicillin	1500 cc of blood	Local tetanus near one wound in leg, mild pulmonary atelectasis and serum sickness	Recovery
6	Compound fracture of left tibia	5	1 cc. of toxoid on day of injury and 3000 units of antitoxin 4 days after injury	Amputation of left lower leg	30 000	110 000	44 gm. of sulfadiazine and 1 000 000 units of penicillin	500 cc of plasma and 4000 cc. of blood	Severe atelectasis of both lungs with pneumonia, laryngospasm, alkalotic tetany(?) and oliguria	Recovery
7	Lacerating wound of right thigh, with foreign body	11	0.5 cc. of toxoid on day of injury and 1500 units of antitoxin 9 days after injury	Redebridement		120 000	34 gm. of sulfadiazine and 640 000 units of penicillin	None recorded	Oliguria, spasms of bladder sphincters and mild pulmonary atelectasis	Recovery
8†	Multiple lacerating wound of left buttock, thigh and right leg and compound fractures of toes of left foot	10	1500 units of antitoxin 6 days after injury	Redebridement	10 000	110 000	12 gm. of sulfadiazine and 1 120 000 units of penicillin	1500 cc. of blood	None recorded	Recovery
9	Severe burns of face, arms and neck	8	750 units of antitoxin 5 days after injury	Redebridement and removal of powder particles	40 000	110 000	40.5 gm. of sulfadiazine and 1 280 000 units of penicillin	500 cc. of plasma and 5300 cc. of blood	Bleeding from debrided areas	Recovery
10	Compound fracture of tibia and fibula and two penetrating wounds of left thigh, with foreign body	10	1500 units of antitoxin 1 day after injury	Redebridement		180 000	45 gm. of sulfadiazine and 980 000 units of penicillin	500 cc. of plasma and 2000 cc. of blood	Abdominal distention, bladder-sphincter spasms, pulmonary atelectasis, severe (?) tetanus) spasm resulting in death and extensive pulmonary atelectasis with intrapulmonary hemorrhages found at autopsy	Death on seventh day of treatment

*This patient had generalized tetanus, with especially severe local tetanus in one leg.

†Symptoms began as local tetanus in one leg for 4 or 5 days and muscle spasm finally spread to whole body.

the Orient and other endemic areas may be expected to occur in the future on an ever-increasing scale. Although vaccination will be required in international travel, improperly vaccinated persons may arrive while in the incubation period of the disease and may travel far inland before recognizable symptoms occur. The only foolproof countermeasure is for civilian communities to maintain a high level of group immunity by sustained and comprehensive vaccination programs.

SUMMARY

Data regarding the occurrence of tropical diseases in the armed forces during the wartime period of 1942 to 1945 inclusive are presented. Of the diseases usually termed "tropical," those of a major occurrence in men who served overseas, in order of frequency, were dysentery, malaria, infectious hepatitis and dengue. The incidence of all other tropical diseases contracted during this period was remarkably small considering what had been anticipated in view of overseas exposure in highly endemic areas.

The points of greatest postwar significance to civilian public-health and medical practice in general appear to be the following:

There is small likelihood, despite the high wartime prevalence of dysentery, that chronic disability will occur in any large number of veterans or that

there will be a significant spread of bacillary infections in civilian communities.

The end of the once serious problem of malaria appears to be in sight. The vast majority of recurring malarial infections have expended themselves. Although significant spread of the disease in civilian communities appears not to have occurred to date, the improved situation still does not warrant a relaxation of control efforts.

The large-scale occurrence of infectious hepatitis during wartime may result in postwar problems of continuing gravity. The essential danger is dissemination incident to the therapeutic use of blood and blood derivatives.

Intensive measures have been undertaken by the armed forces to prevent the further occurrence of smallpox epidemics such as have already appeared in two civilian communities. Modern rapid civilian air travel presents a future danger of smallpox introduction against which the surest countermeasure for civilian communities is comprehensive smallpox vaccination.

NOTES ON THE TREATMENT OF TETANUS

JOHN R. GRAHAM, M.D.,* AND T. MCNAIR SCOTT, M.D.†

BOSTON AND PHILADELPHIA

PROPHYLAXIS against tetanus by means of active immunization with tetanus toxoid reduced the incidence of this disease among wounded United States Army personnel to a low figure. Only 1 case of tetanus had been reported in the European Theater by February 1, 1945. In the German Army, however, active immunization by means of toxoid was given only to those who stood the greatest chance of being wounded far from their own lines, such as members of the *Luftwaffe* and paratroops. The great mass of the German Army received no active immunization and had to depend for protection on the passive immunity supplied by tetanus antitoxin administered at the time of wounding. As a result, tetanus was frequently encountered in German prisoner casualties treated in United States military hospitals. Since the rarity of the disease among American soldiers has denied many American physicians the opportunity of dealing personally

with its many problems, it seems worthwhile to present our experience gained in the care of 10 cases of tetanus that developed among the 3507 sick and wounded German prisoners treated at an overseas station hospital between September, 1944, and March, 1945. A summary of the clinical course of each of these patients is presented in Table 1. Some of the important points regarding the clinical problems and therapeutic management are discussed below.

Incubation Period

The incubation periods ranged from five to twenty-two days, with an average of slightly over ten days. Although in this series no correlation could be made between the length of the incubation period and the mortality, because of the variable factor of antitoxin administration before the onset of the disease, it is interesting that all the deaths occurred with incubation periods of ten days or less. It should be noted, however, that 3 of the 6 survivors had short incubation periods—ten, eight and five days, respectively.

the differential diagnoses to be considered include mumps, peritonsillar abscess, affections of the temporomandibular joint, trismus following tooth extraction, a wound involving the mouth and jaws directly, and tetanus. The presence of the first one of these conditions may be readily determined. In their absence tetanus must be considered the diagnosis. In addition to lockjaw, the patient will probably show tenseness of the face muscles producing the risus sardonicus, as well as increased tonus of the sternocleidomastoid muscles, which makes them easily palpable even when the patient's head is lying relaxed on his pillow. Continuous spasm and rigidity of the abdominal muscles may already have developed or may soon follow. Usually accompanying these signs are fever, profuse sweating, extreme mental apprehension and beginning difficulties in swallowing and expectorating. The muscle spasm and rigidity gradually spread over the whole body, opisthotonos develops and the patient becomes "as stiff as a wooden Indian." Sudden, severe local spasms or generalized convulsions, superimposed on the continuous muscle rigidity, are caused by such external stimuli as noise, changing the bed or dressing the wound.

The onset of tetanus beginning with local symptoms is characterized by increasing irritability of the muscles in one part of the body—usually in the vicinity of a wound—that develops several days after injury. At first, the patient may complain only of painful intermittent cramps in the involved region. Within a day or so the cramps become more and more frequent and are brought on by weak stimuli, such as merely touching the bedclothes or exposing the patient to a cold draught. Gradually, the whole group of muscles in the neighborhood of the wound shows continuous spasm. These muscles are tense and firm at all times, and merely touching them produces a severe spasm of the whole extremity and possibly of the contralateral extremity as well. Following this, generalized tetanus often develops. It is necessary and difficult to differentiate this form of tetanus from local muscle spasm resulting from direct injury to muscle or nerve. In general, spasm resulting from direct injury may be expected to decrease a few days after the wound, whereas that from tetanus usually begins only after the first few days have passed. In doubtful cases the condition should be treated as if it were tetanus.

The initial symptom in one patient (Case 8) was local spasm in one leg that was not diagnosed for four days. Even after treatment was started, signs of generalized tetanus of a mild sort developed. One patient with generalized tetanus (Case 5), who had had six major wounds débrided at the onset of symptoms, showed maximum muscular spasm in the vicinity of a seventh wound, which had not been débrided because of its apparent insignificance. Because of the persistence of this local irritability,

débridement was subsequently performed, and a dirty piece of uniform was removed from this small but deep wound.

Bacteriology

Little help in the practical management of a case of tetanus can be obtained from culture of the wounds for *Cl. tetani*. In many war wounds, bacilli are found that resemble *Cl. tetani* morphologically but are nonpathogenic organisms. Furthermore, proved *Cl. tetani* can be cultured from about 20 per cent of all war wounds in the absence of clinical tetanus. The isolation and identification of the organism take too long to be of help in early diagnosis.

Treatment

Before the treatment of a case of tetanus is begun, it is well for the physician to have a clear conception of the magnitude, complexity and duration of the problem confronting him. The patient will usually have an operation under anesthesia for redébridement of his wound. He will be seriously ill for ten days or two weeks and almost completely helpless. In addition to the pain, spasms, muscular rigidity and mental apprehension produced by tetanus, the patient usually suffers from a serious wound, which in itself requires expert surgical or orthopedic attention and which may already have disturbed the bodily economy by means of infection and loss of protein, hemoglobin and electrolytes. As a result, the fluid, electrolyte, caloric and protein requirements are excessive, and yet the patient cannot eat and drink in the ordinary way. He may be incontinent of urine and feces. He is subject to all the allergic reactions consequent to the administration of antitoxin, as well as to dangerous complications at every turn that may demand immediate intervention. In view of these facts, adequate preparation must be made from the beginning to meet successfully the difficulties ahead.

In the first place, special attendants must be selected to care for this patient, and this patient alone, day and night. They should be the most reliable, observant and steady personnel available. Secondly, a suitable place, apart from other patients and visitors, should be selected. It is best to have one room for the patient and another for the attendant. These rooms should be equipped with all the materials necessary for the care of the patient, so that they form a unit in which the personnel may function free from the delays of ordinary hospital procedure.

Having arranged for suitable personnel and a properly equipped place for the care of the patient, the physician should outline a definite schedule of treatment on an hourly timetable. Many treatments, medications, dressings and procedures of one sort or another should be scheduled in groups

Mortality

Of the 10 patients treated, 4 died. The first 3 patients died within three or four days of the onset of symptoms, the other patient died suddenly on the seventh day of treatment, at a time when he appeared to be recovering. Other factors besides the length of the incubation period undoubtedly played a role in the successful outcome of those who recovered. Chief among these, in our opinion, was the factor of increased experience in handling the problem gained during treatment of the first 3 fatal cases. Another factor may well have been the larger amounts of antitoxin given to those who recovered.

Prophylaxis

Data covering the time, type and amount of specific prophylaxis were available in 9 of the 10 cases. In none of these had the prophylaxis been satisfactory. The rules governing proper prophylaxis are as follows: a person who has already been actively immunized by tetanus toxoid should receive a booster dose of 1 cc. at the time of injury — it is useless to give a so-called "wound dose" of toxoid to a person who has not been previously actively immunized, because the development of antibodies from the first dose is too little and too late to prevent the occurrence of the disease, a patient who has not been actively immunized must be given passive immunity by means of tetanus antitoxin at the time of injury. Experience in World War I demonstrated that the amount of antitoxin should be 1500 (American) units and that it should be given, if possible, on the day of the wound and repeated at weekly intervals for a total of three doses. The passive immunity created by the administration of one dose of 1500 units of antitoxin is protective for only seven to fourteen days, and unless this dose is repeated, as recommended above, tetanus develops in a certain number of cases. In the patients studied by us, the following deviations from these recommended procedures were noted: in Case 2 a dose of 1500 units of antitoxin was given, but not until the fifth day after injury, and tetanus developed on the eighth day, in Case 3, instead of antitoxin, 0.5 cc. of toxoid was given on the day after the wound was received, and tetanus developed on the tenth day, in Case 4 a total of 1500 units of antitoxin was given, but not until the eighth day after wounding, and tetanus developed on the fourteenth day, in Case 5 a dose of 1500 units of antitoxin given on the first day was not repeated, and tetanus developed on the twenty-second day, in Case 6, instead of antitoxin, 1 cc. of toxoid was given on the day of injury, and tetanus developed on the fifth day in spite of 3000 units of antitoxin finally given on the fourth day, in Case 7, instead of antitoxin, 1 cc. of toxoid was given on the day of the wound, and tetanus developed on the eleventh day in spite of 1500 units of antitoxin finally given on the ninth day, in Case 8 a

dose of 1500 units of antitoxin was given, but not until the sixth day, and tetanus developed on the tenth day, in Case 9 only 750 units of antitoxin were given, — on the fifth day, — and tetanus developed on the eighth day, in Case 10 a dose of 1500 units of antitoxin was given on the second day, but was not repeated, and tetanus developed on the tenth day.

Failures to give proper specific prophylaxis to these patients were undoubtedly due to battlefield conditions. They nevertheless serve to illustrate the value of administering antitoxin to unimmunized personnel early, in proper amounts and with repeated doses.

Nine of the 10 patients had received considerable amounts of both penicillin and sulfadiazine for wound infection prior to the development of tetanus. One patient had received as much as 1,000,000 units of penicillin and 30 gm. of sulfadiazine, and another had received 400,000 units of penicillin and 40 gm. of sulfadiazine. These facts offer suggestive evidence that modern chemotherapeutic agents cannot be relied on — at least in the amounts mentioned — to prevent the development of the disease.

Type of Wound

Seven patients had compound fractures, 2 had penetrating flesh wounds, and 2 had severe burns. The following points need emphasis: the eschar of a contaminated burn creates ideal anaerobic conditions for the development of *Clostridium tetani*, and a small penetrating wound harboring pieces of dirt and clothing may prove more fertile soil for the organism than the larger and more dramatic wound that, in the normal course of events, attracts greater attention from the surgeon.

Diagnosis

The most important step in the diagnosis of tetanus is to think of it. Even after a case has occurred in a hospital and the staff has become alerted, the signs and symptoms are apt to be missed for twenty-four hours. Suspicion is often aroused by a nurse or ward attendant who calls the medical officer's attention to the fact that a patient is having difficulty in eating or in placing a thermometer into his mouth.

The speed with which tetanus develops from onset to clearcut symptomatology varies greatly from patient to patient. When the disease is fulminant, signs may be observed within a few hours of onset. Conversely, mild local tetanus may smolder along as local muscle spasm in the vicinity of a wound for several days before the appearance of spasm in other muscles makes the diagnosis unequivocal.

The so-called "lockjaw phenomenon" is usually the first overt sign and symptom of classic generalized tetanus. When a wounded man complains that he is having difficulty in opening his mouth,

proteins had been an important cause of death. As a result, studies of plasma protein, hemoglobin and hematocrit values were made, and in many cases these were found to be lowered. To such patients large amounts of plasma and whole blood were given intravenously in an effort to restore these values to normal. One patient received 5300 cc of blood and 500 cc. of plasma, and several others received 1500 to 2000 cc of blood.

Our observations led us to believe that these vigorous efforts to meet abnormally great nutritional demands were helpful both in supporting the patient through the critical stage of the disease and in shortening the period of convalescence.

Complications

Convulsions The prevention and treatment of convulsions involved nice judgment in the use of sedation, and it was soon found that the course to be followed was treacherous. On the one hand, too little sedation left the patient exposed to the dangers of severe spasms and convulsions. In one patient (Case 6) who was too lightly sedated spasm of the larynx with severe stridor relaxed only when the patient appeared on the point of death. Thereafter a tracheotomy set was kept in the treatment room. The last patient of the series (Case 10) appeared to be doing well on the seventh day when a sudden generalized convulsion occurred and the patient became extremely cyanotic and died in spite of all attempts at resuscitation, at autopsy, extensive atelectasis and intrapulmonary hemorrhages were found. On the other hand, it soon became obvious that too much sedation increased the danger of serious pulmonary complications. The patient with tetanus can scarcely expectorate through his clenched teeth and can take only shallow breaths, owing to the rigidity of the chest muscles. These factors alone render the patient easy prey to pulmonary atelectasis. When sedation is added in amounts sufficient to depress respiration and the cough reflex, the susceptibility to pulmonary complications is still further increased.

To avoid these two extremes, it was found advisable to give a regularly scheduled dose of sedative sufficient to blunt the edge of apprehension and keep the patient drowsy a good deal of the time without narcotizing him so deeply that he became difficult to arouse. Temporary increases in this basal dose were made whenever severe spasms threatened and before stimulating procedures, such as dressing the wound and replacing a stomach tube, were carried out. It proved imperative on several occasions also to have immediately available a parenteral sedative of the quick-action type.

Of the many sedatives suggested for use in the treatment of tetanus, we selected two and can report on them as being satisfactory. Paraldehyde met all the requisites: it could be given by mouth

or by rectum for prolonged basal sedation; it could be taken directly from the bottle into a syringe for intramuscular or intravenous injection to gain an immediate effect in an emergency, 4 to 6 cc of paraldehyde every three hours by mouth—or by means of a stomach tube—produced about the desired amount of basal sedation in most cases, and 2 to 4 cc intravenously or intramuscularly supplied rapid sedation successfully. The other sedative used was sodium amytal, which could be given by mouth in doses of 0.2 gm every three hours for basal sedation or by vein in doses of 0.3 gm for emergencies. After three or four days the patient's tolerance to these drugs usually showed a definite increase and the dosage was raised or a shift to the alternate sedative effected.

Since the aim is to give as little sedation as is consistent with protection from convulsive seizures, it is essential that the greatest advantage be taken of the sedation produced by the scheduled doses. Routine procedures involving handling of the patient should be so timed that they occur when the effect of the regularly scheduled dose is at its peak. By this means, extra doses may be avoided.

Infection To 8 patients, full doses of sulfadiazine (with equal amounts of sodium bicarbonate) were given by mouth, and 20,000 units of penicillin were given intramuscularly every three hours for three to seven days. These drugs were used for their bacteriostatic effect both on the tetanus bacillus and other pathogenic wound organisms and on pathogens in the respiratory tract to prevent pulmonary infection following atelectasis. In 2 patients (Cases 4 and 6) sulfadiazine was stopped because of a marked decrease in renal output. In one of these (Case 6) the drug was resumed with beneficial effect when pneumonia supervened.

Miscellaneous Since pulmonary atelectasis of minor or major degree was an almost universal complication, frequent turning of the patient in bed, voluntary coughing and intermittent inhalation of a mixture of 5 per cent carbon dioxide and 95 per cent oxygen were instituted as routine procedures for two or three days following operation. When atelectasis developed, care was taken that the affected lobe or lobes received frequent postural drainage. Several firm slaps on the back, with the patient turned on his face or lifted up by the hips, were helpful in some cases in loosening mucous plugs in the bronchial tree. Bronchoscopy and tracheal catheterization were not employed for fear that the local laryngeal irritation caused by these procedures might induce laryngeal spasm. Atelectasis, which was so widespread in 1 case that oxygen therapy by means of a B.L.B. mask was given for two days, in most cases proved an extremely troublesome and serious complication.

Two patients (Cases 7 and 10) suffered from retention of urine from spasm of the bladder sphincters. Inlying catheters were used for a few

so that several things are done at once and time is allowed for the patient to have uninterrupted rest for the succeeding interval. A three-hour schedule proved satisfactory in our hospital. The patient may be given sedation, penicillin, feeding, back massage, postural changes and intravenous therapy, if indicated, at intervals of three hours. After the first 3 cases, we learned that it was well worth while to have a mimeographed form on which there was space for every hour of the day and night for recording the therapy that was ordered and carried out. When these forms had been completed, they were filed chronologically in the attendant's room so that the medical officer could easily refer to them.

The main principles of treatment adopted were as follows: sufficient antitoxin was given to the patient to neutralize the effects of toxin that had been and was still being produced, so far as possible, the focus at which tetanus toxin was still being produced was removed, attempts were made to prevent and treat the complications of the disease, and general supportive treatment was given.

The administration of antitoxin involves a decision regarding the amount of antitoxin to be given and the route and speed of its administration. The factors affecting this decision are the length of the incubation period and the severity and rapidity of progression of the symptoms. Patients who had had a short incubation period and fulminating symptoms were considered to require large amounts of antitoxin, about one quarter of the total dose being given intravenously. In the slowly progressive form, in which mild symptoms developed over two or three days, we gave all antitoxin intramuscularly and in smaller amounts.

In the first 3 cases 70,000 to 80,000 (American) units of antitoxin was given—20,000 to 40,000 intravenously and the rest intramuscularly. The 3 patients died. These unfortunate results induced us to use between 120,000 and 180,000 units of antitoxin in the subsequent 7 cases, in this group, only 1 patient died. In 5 of these cases fulminating symptoms led us to give 20,000 to 40,000 units intravenously. The remainder was injected partly into the muscles in the vicinity of the wound and partly into the gluteal or thigh muscles. In all cases the great bulk of the antitoxin was administered as soon as possible after the diagnosis of tetanus had been made, usually during the operation for débridement of the wound. In 3 patients further progression of symptoms and a feeling of doubt concerning the elimination of the focus, such as widespread burns, induced us to give additional doses in the course of the ensuing week. Whenever antitoxin was administered, adrenalin in a syringe was available for immediate use.

The usual procedure was to perform a skin test for sensitivity to horse serum as soon as the diagnosis had been established. During the twenty minutes that were necessary for the observation of

the reaction to this test, the operating theater was alerted to make ready for débridement of the wound, and the previously selected personnel were summoned to prepare the rooms and equipment for the subsequent care of the patient. The allotted dose of antitoxin was administered during the operation.

Radical débridement of every wound was performed under intravenous Pentothal Sodium anesthesia. This is necessary, in our opinion, despite a history or evidence of previous débridement and despite the innocent appearance of slight wounds. Amputation, in 3 borderline cases, was considered justified, since the immediate threat to life from a residual focus of tetanus outweighed the handicap of a permanent deformity. In a patient with extensive burns it was considered necessary to employ widespread, meticulous surgical removal of necrotic tissue even despite the risk of some secondary hemorrhage. This was followed by activated zinc peroxide dressings, which were changed under anesthesia every two or three days until the areas remained clean. Postoperative wounds were usually dressed with penicillin compresses and in some cases with activated zinc peroxide.

When the patient was wheeled from the operating theater, two major steps in therapy had been accomplished: the focus of tetanus toxin production had been removed so far as was possible and the patient had received a large amount of antitoxin to offset the effects of toxin that had already been produced.

The caloric, protein, electrolyte and fluid requirements of the patient with tetanus are large because of high fever, constant muscle spasm, excessive sweating, infection, and loss of plasma and blood from the wound. To meet these demands, a stomach tube was introduced shortly after the patient's arrival from the operating room. By this route were subsequently given a daily diet of 3000 to 3500 calories containing 120 to 130 gm of protein and 3500 to 4000 cc of fluid. The tube proved an invaluable method of giving not only these nutrients but also medications such as sulfonamides, vitamins, sedatives and mineral oil. By the use of a tube of sufficient length, all these procedures could be effected without even waking the patient from sleep. It is difficult to get a tube in place in a patient with tetanus. We found it helpful to carry out this procedure shortly after a sedative had been given, when the patient's apprehension had been dulled and yet before the sedative had taken such effect that the patient was no longer co-operative. Once the tube was in place, our practice was to leave it there five or six days without renewal, since reinsertion often precipitated convulsive seizures. Evidence at autopsy, in an early and rapidly fatal case, of widespread tissue edema, in addition to pulmonary edema and pleural effusion, attracted our attention to the possibility that low plasma

proteins had been an important cause of death. As a result, studies of plasma protein, hemoglobin and hematocrit values were made, and in many cases these were found to be lowered. To such patients large amounts of plasma and whole blood were given intravenously in an effort to restore these values to normal. One patient received 5300 cc of blood and 500 cc. of plasma, and several others received 1500 to 2000 cc of blood.

Our observations led us to believe that these vigorous efforts to meet abnormally great nutritional demands were helpful both in supporting the patient through the critical stage of the disease and in shortening the period of convalescence.

Complications

Convulsions The prevention and treatment of convulsions involved nice judgment in the use of sedation, and it was soon found that the course to be followed was treacherous. On the one hand, too little sedation left the patient exposed to the dangers of severe spasms and convulsions. In one patient (Case 6) who was too lightly sedated spasm of the larynx with severe stridor relaxed only when the patient appeared on the point of death. Thereafter a tracheotomy set was kept in the treatment room. The last patient of the series (Case 10) appeared to be doing well on the seventh day when a sudden generalized convulsion occurred and the patient became extremely cyanotic and died in spite of all attempts at resuscitation, at autopsy, extensive atelectasis and intrapulmonary hemorrhages were found. On the other hand, it soon became obvious that too much sedation increased the danger of serious pulmonary complications. The patient with tetanus can scarcely expectorate through his clenched teeth and can take only shallow breaths, owing to the rigidity of the chest muscles. These factors alone render the patient easy prey to pulmonary atelectasis. When sedation is added in amounts sufficient to depress respiration and the cough reflex, the susceptibility to pulmonary complications is still further increased.

To avoid these two extremes, it was found advisable to give a regularly scheduled dose of sedative sufficient to blunt the edge of apprehension and keep the patient drowsy a good deal of the time without narcotizing him so deeply that he became difficult to arouse. Temporary increases in this basal dose were made whenever severe spasms threatened and before stimulating procedures, such as dressing the wound and replacing a stomach tube, were carried out. It proved imperative on several occasions also to have immediately available a parenteral sedative of the quick-action type.

Of the many sedatives suggested for use in the treatment of tetanus, we selected two and can report on them as being satisfactory. Paraldehyde met all the requisites: it could be given by mouth

or by rectum for prolonged basal sedation, it could be taken directly from the bottle into a syringe for intramuscular or intravenous injection to gain an immediate effect in an emergency, 4 to 6 cc of paraldehyde every three hours by mouth—or by means of a stomach tube—produced about the desired amount of basal sedation in most cases, and 2 to 4 cc intravenously or intramuscularly supplied rapid sedation successfully. After three or four days the patient's tolerance to these drugs usually showed a definite increase and the dosage was raised or a shift to the alternate sedative effected.

Since the aim is to give as little sedation as is consistent with protection from convulsive seizures, it is essential that the greatest advantage be taken of the sedation produced by the scheduled doses. Routine procedures involving handling of the patient should be so timed that they occur when the effect of the regularly scheduled dose is at its peak. By this means, extra doses may be avoided.

Infection To 8 patients, full doses of sulfadiazine (with equal amounts of sodium bicarbonate) were given by mouth, and 20,000 units of penicillin were given intramuscularly every three hours for three to seven days. These drugs were used for their bacteriostatic effect both on the tetanus bacillus and other pathogenic wound organisms and on pathogens in the respiratory tract to prevent pulmonary infection following atelectasis. In 2 patients (Cases 4 and 6) sulfadiazine was stopped because of a marked decrease in renal output. In one of these (Case 6) the drug was resumed with beneficial effect when pneumonia supervened.

Miscellaneous Since pulmonary atelectasis of minor or major degree was an almost universal complication, frequent turning of the patient in bed, voluntary coughing and intermittent inhalation of a mixture of 5 per cent carbon dioxide and 95 per cent oxygen were instituted as routine procedures for two or three days following operation. When atelectasis developed, care was taken that the affected lobe or lobes received frequent postural drainage. Several firm slaps on the back, with the patient turned on his face or lifted up by the hips, were helpful in some cases in loosening mucous plugs in the bronchial tree. Bronchoscopy and tracheal catheterization were not employed for fear that the local laryngeal irritation caused by these procedures might induce laryngeal spasm. Atelectasis, which was so widespread in 1 case that oxygen therapy by means of a B.L.B. mask was given for two days, in most cases proved an extremely troublesome and serious complication.

Two patients (Cases 7 and 10) suffered from retention of urine from spasm of the bladder sphincters. Inlying catheters were used for a few

days for relief of this symptom and to prevent constant changing of bed linen because of incontinence

Fecal impaction occurred in Case 4. The severe muscle spasms that were caused by its manual extraction induced us to give 30 cc of mineral oil, through the stomach tube, each night as a routine procedure to all subsequent patients. No other impactions developed.

SUMMARY

The experience in treating 10 cases of tetanus among German prisoners of war is reported. Of these 10 patients, 4 died.

The problems of tetanus prophylaxis are discussed and the necessity of adequate and repeated doses of prophylactic antitoxin in previously unimmunized personnel is stressed. The value of considering even slight wounds as possible foci of infection is pointed out, and some of the difficulties in diagnosis are discussed.

Attention is drawn to the difficulty of the therapeutic problem, and the management of these cases is described in detail, with emphasis on the importance of teamwork and constant individual attention for good therapeutic results.

PLASTIC SURGERY IN A MILITARY HOSPITAL*

RADFORD C. TANZER, M.D.†

HANOVER, NEW HAMPSHIRE

ORGANIZATION

The cases were divided into the following five general groups: maxillofacial, hand, orthopedic, eye, and general plastic.

Maxillofacial Section

These cases comprised all requiring the combined services of a plastic and a dental surgeon. The predominant type consisted of missile wounds of the mandible and maxilla, with a smaller percentage of fractured jaws due to vehicle injuries. There were also occasional cases of mandibular tumor and cyst, palatal defects and other abnormalities encountered in civilian life.

As soon as a history had been obtained and physical and x-ray examination had been completed, the patient was presented before a conference composed of a plastic surgeon, a dental surgeon and a liaison officer, the last being the ward officer directly in charge of all maxillofacial cases. At that time a program of treatment was outlined. In missile wounds of the jaws this usually consisted of the determination of the type of splint to be applied and a decision regarding the need for sequestrectomy. The patient was then followed in either the dental or the surgical department until the next phase of treatment, when he was again presented before the conference. At this stage the question of the need for a bone graft usually arose. When nonunion was evident the type of fixation and the kind of graft were determined. Iliac bone was used in most cases, although in cases of mild nonunion osteoperiosteal grafts sufficed. Rib grafts were occasionally employed to reconstruct fractures in the region of the angle or horizontal ramus.

The dental surgeon usually assisted at the operation and carried out postoperative oral care. Several weeks later the patient was again presented before

IN 1944 the Cushing General Hospital was designated as one of nine Army centers for plastic surgery operating within the continental limits of the United States. During the first twenty months a total of 1474 patients were admitted to this section, and two thousand one hundred and ninety-six operative procedures were carried out, with no operative or postoperative mortality.

The organization and functioning of this center is of interest, not only from the standpoint of its military pattern but also because of methods and procedures, developed in the face of reduced personnel, that might prove advantageous in the operation of any civilian hospital service. Also, military medicine has impressed on its participants the value of frequent consultation in the care of patients—a type of practice to which army medicine lends itself quite easily because of the concentration of patients, even with minor illnesses, in hospitals. This concept of directing the care of patients, which had previously been utilized to advantage at the Bushnell General Hospital, was expanded at this post to include the care of the majority of the plastic surgical cases.

The lack of trained personnel, as well as the frequent change, necessitated the most efficient utilization of the time of the two trained plastic surgeons and of those who had received special instruction. For this reason the cases were divided into several groups for the purpose of concentrating the care of patients in each of these categories and also for expediting the training of nurses and corpsmen by familiarizing them quickly with problems arising in the particular group under their jurisdiction.

*Delivered at the postponed annual meeting of the New England Surgical Society, Boston, January 15, 1946.

†Instructor in surgery, Dartmouth Medical School, plastic surgeon, Hitchcock Clinic, formerly, chief of plastic and maxillofacial surgery, Cushing General Hospital, Framingham, Massachusetts.

the conference to determine the stability of the graft and the need for further surgery prior to preparation of dentures. If the dentist considered the buccal or labial sulci inadequate, an epithelial inlay was scheduled, the dentist preparing a fixation splint for the stent prior to operation. Again, the dentist assisted at the operative procedure and carried out oral care during the convalescence, introducing a denture as soon as the grafts were stable.

Under this program the simultaneous care of the patient by two departments was closely integrated. With the plan for each patient outlined and recorded in the conference, loss of time was avoided and, of more importance, the operative procedures of both departments were correlated. Cases such as those with injudicious extraction of teeth needed for splint support in palatal repair or bone graft were reduced to a negligible number. During periods of change of personnel, the conference furnished a means of maintaining the continuity of treatment by both departments until new officers had acquired a grasp of the problems involved. It was the opinion of all concerned that the conference created a most harmonious environment that was mutually instructive and effectively eliminated the misunderstandings incident to a more remote type of collaboration.

Hand Section

A similar conference was set up for the administration of several hundred cases of hand injury. The predominant injury was the gunshot or shell-fragment wound, with a smaller group of burn scars and vehicle injuries.

The conference was directed by four persons, including plastic, neurosurgical and orthopedic surgeons and a physiotherapist. After initial study each case was presented before the conference, where a course of treatment was outlined and the patient sent to the appropriate ward. A majority of the patients with missile injuries were retained on the plastic wards because of a resurfacing problem. Occasionally, the defect could be covered by rotation of local tissues, but in most cases abdominal flaps—either tubed or direct—were utilized to cover the involved areas. In a few of the smaller defects around the web spaces, flaps from the opposite arm were employed. As soon as the resurfacing had been completed, the patient again appeared before the conference for review and was transferred either to the orthopedic service for tendon and bone work or in some cases to the neurosurgical service for nerve repair. It was often arranged in conference to have two services carry out a combined procedure, such as a nerve exploration or repair with a rotation or pedicle flap.

The patients with hand deformities resulting from burns were treated primarily on the plastic service, where resurfacing with free grafts was carried out as quickly as possible. These cases were also fol-

lowed in conference, where the counsel of the orthopedic surgeon in methods of splinting to minimize deformity was most valuable and where the presence of the physiotherapist integrated the surgical procedures with the graduated exercise that had to be started in the early postoperative course.

As time went on, each member of the conference became familiar with the usual methods of treatment proposed by the other members, and a number of modifications of therapy were carried out as a result of the integration of individual concepts of treatment. For example, the plastic surgeon's emphasis on the susceptibility of recent grafts to trauma led the physiotherapist to modify the treatment of this group of hand cases. All new technicians were carefully warned of the danger of too forceful massage, and the use of infrared lamps and whirlpool baths at the usual temperature was eliminated.

Orthopedic Section

This group of cases was composed mainly of missile wounds of the lower extremity, presenting some of the most trying problems in rehabilitation. The great majority of patients had been admitted on the orthopedic service, where the initial phase of treatment, consisting of the application of traction and casts and the exploration of draining wounds and sinuses, had been carried out. As soon as feasible many of these patients were brought to a conference composed of an orthopedic and a plastic surgeon, where the former surgeon presented his opinion of the type of bone and tendon reconstruction that would be needed in the future and the latter outlined a plan of resurfacing to permit the maximum surgery that might be anticipated.

Occasionally, free grafts were sufficient, but the average case required a much more stable integument, so that the usual recommendation for coverage was a direct pedicle flap transferred from the opposite leg or thigh. A few defects were in such a position or of such magnitude that the cross leg graft was not appropriate, and thoracoepigastric tubed pedicle flaps brought down via the wrist were necessary. Again, combined procedures were sometimes decided on. Rotation flaps to cover bony defects could be combined with iliac bone chips to fill depressed areas, either to increase stability of the affected bone or to fill cavities that could not be completely obliterated by the rotated flap. In multiple injuries two teams—an orthopedic and a plastic—arranged to carry out separate procedures on the same patient simultaneously.

Eye Section

Although comprising a smaller group than the ones mentioned above, the cases of missile wounds of the orbit presented rather complex problems for the integration of functions of the ophthalmologist, neurosurgeon, plastic surgeon and the ocular pros-

thetic department. Many of these patients had suffered loss of a portion of the bony wall of the orbit, with or without involvement of the dura. Patients in whom the only problem was restoration of bony contour of the supraorbital or latero-orbital region were treated on the neurosurgical service, usually by the introduction of a moulded tantalum or lucite plate. When there was associated deformity of the soft tissues of the orbit, it was usual to carry out reconstruction of the lids and conjunctival sacs before the tantalum plate was introduced.

The intraorbital reconstruction was planned in conjunction with the ophthalmologist and the dental surgeon in charge of the construction of acrylic prostheses. In general, the first problem was replacement or reconstruction of the lids. Adjacent flaps or free grafts were used in almost every case, to afford external covering, with the introduction of ear cartilage when necessary to provide support. The adequacy of the conjunctival sac was then evaluated. Occasionally, in questionable cases, the prosthetist was able to dilate a sac of borderline dimensions with graduated conformers and to obviate the need for grafting. In the severer injuries mucous-membrane grafts were introduced to enlarge the socket, and as soon as the graft was healed, the patient was transferred to the prosthetic department, where a conformer was inserted immediately to prevent contracture of the graft. While the final prosthesis was being constructed, minor revisions such as eyelash grafts were carried out.

General Plastic Section

In all cases that did not fall into the special categories listed above the patients were admitted to a general plastic section, where there was no significant duplication with other surgical fields.

Many cases of severe facial burn presented problems in the reconstruction of deformed ears, partial nasal loss, lip contractures and loss of cheek, forehead and orbital skin. Ear reconstruction was performed by the use of adjacent retroauricular skin when the loss was confined to the helix, in more extensive losses, it was necessary to restore cartilage support by means of preserved rib cartilage taken during autopsies and kept under sterile conditions until needed. If the retroauricular skin had been severely damaged by the original trauma, the scar was replaced by a free skin graft, which was later used for the auricular reconstruction.

Preserved cartilage was also used extensively for building up depressions of the infraorbital ridge and malar region. These fractures were well consolidated by the time of arrival at the hospital, so that no attempt at repositioning was made, even in cases in which no loss of substance had occurred. Cartilage was used both in the form of carved blocks and in the form of diced material, and occasionally in combinations of the two.

Nasal deformities varied from relatively minor losses from burns to total nasal loss due to shell fragments. The small losses of the alar rim were restored by free grafts from the rim of the ear, including a strip of cartilage for support. The more extensive losses required either pedicle flaps from the forehead or tubed flaps from the cervical or humeral regions.

Deformities about the mouth at times presented complex problems in reconstruction. Whenever possible the reconstruction was performed by rotating skin from the adjacent cheek or cervical region to afford a covering that most closely matched in color* and texture the absent tissues. Occasionally the defect was too extensive for such procedures and tubed pedicle flaps from the lower neck, acromipectoral region or thoracoepigastric region were utilized.

Operating and Dressing Rooms

To utilize to the maximum degree the available time of the trained members of the staff, it was frequently possible to have two teams supervised by one plastic surgeon. This was not considered in any sense an ideal situation but offered a practical expedient to aid in keeping up with the required work. Furthermore, it was considered essential to eliminate so far as possible all delay between operative cases.

The preparation of a plastic case for operation often requires a good deal of time—for example, when, to resurface a hand, the affected hand and forearm and the donor area, such as the abdomen, chest or thigh, must be prepared. To eliminate the delay of preparing a patient in the operating room, the following routine was established. After a period of instruction, a nurse selected as the supervisor of preoperative preparation was able to acquire a firm grasp of the principles involved in the preparation of plastic patients. Corpsmen were assigned to function under her jurisdiction. Patients arriving at the operating pavilion were taken to a preparation room where a detailed description of the field of operation, submitted by the surgeon on the operative slip, was available. All operative fields were shaved, thoroughly cleansed with soap, alcohol, ether and Zephiran and covered with sterile towels, the patient being retained in the preparation room until an operating room was free, when he was transferred to an operating table and the draping was completed. In the preparation of facial cases, pontocaine drops were administered to the eyes to prevent discomfort. In this way it was possible to

*Facilities eventually became available for the artificial pigmentation of scars and grafts conspicuous because of color tones that contrasted sharply with the surrounding tissues. The success of this technique which was essentially the tattooing of the unsightly area with blended mineral pigments depended in large part on the appreciation of color tones and on the ability of the operator to keep the shading on the light side rather than creating an overly dark tone, which was much more difficult to correct. This part of the program was delegated to an artist associated with the department whose previous training in the blending of colors gave him particular qualification in this field.

complete almost all types of preparation before the anesthetic was administered, from ten to forty minutes' delay in the operating room being thus avoided

Another feature that not only saved considerable time but also prevented confusion and omissions in postoperative care was the organization of the dressing section. Two large and completely equipped dressing rooms, as well as two smaller supplementary dressing rooms, were put in operation as soon as possible, and in the great majority of cases post-operative treatment was carried out in these centralized spots. A nurse was placed in charge of the entire dressing section and given the responsibility of training newly assigned nurses in plastic procedures. The dressing nurses worked on a full-time basis in the dressing rooms and did not have ward responsibilities. When the program was well under way, about nine hundred dressings, or 85 per cent of the total number, were carried out weekly by nurses without supervision.

Toward the end of each operation, the operator dictated two sets of instructions, the usual post-operative orders and, on a separate sheet, the dressing orders. Each dressing-order sheet was sent directly to the proper dressing room, where dates of dressings were filed and a list of his own dressings sent daily to each surgeon, delays and omissions in aftercare being thereby eliminated.

SUMMARY

In organizing the plastic surgery section of an Army hospital in the United States, it was found expedient to divide patients into five categories for purposes of administration and professional care. A conference system was established to integrate plastic surgical procedures, with necessary and concomitant treatment by other services, the method of operating these conferences is described. Several practical points in expediting operative and post-operative treatment are discussed.

TOXIC AND HEPATIC FACTORS IN SHOCK

It is now generally agreed that the primary factor in the development of the shock syndrome is a reduction in the effective volume of circulating blood. Whether through hemorrhage, vasodilatation in traumatized regions of the body or loss of fluid through damaged blood vessels in those areas, a discrepancy between the capacity of the vascular system and the amount of blood available to fill it occurs, and the blood pressure falls. If this discrepancy is too great, the body's compensatory mechanisms are overwhelmed, and death quickly follows. With a somewhat lesser degree of oligemia this does not happen, but the blood pressure is more or less rapidly brought back to normal, and spontaneous recovery takes place. In dogs this may occur after bleeding of as much as 30 to 40 per cent of blood volume.³⁹ Somewhere between these two extremes, there appears the condition known as shock in which compensation is adequate only to maintain a prolonged period of hypotension at the end of which the victim finally succumbs. During the greater part of the hypotensive period the condition is reversible, and if adequate replacement therapy is carried out, the animal re-

covers. In the terminal stages, however, the condition becomes irreversible, and despite transfusion or other treatment, recovery does not occur. Much of the recent work on the shock problem has centered around the question of the factors involved in the transition from the reversible to the irreversible stage.

It is clear that continuation of hemorrhage or the further loss of fluid through damaged capillaries in the traumatized region can be and probably is often responsible for the terminal failure of compensation. These factors cannot, however, be the only or even the major ones that operate at this point. Thus, Scott⁴⁰ compared the increase of leg volume in tourniquet shock in dogs and showed that no difference can be demonstrated between the dogs that die and those that recover. The leg volume of dogs that recovered increased on an average by 3.69 per cent of the body weight, whereas in a comparable series of animals dying from early shock the total volume increase was 3.43 per cent of body weight and in a group of animals in deeper shock fatal to all animals, the volume increase was 4.03 per cent of body weight. Friedberg and Katz⁴¹ applied plaster casts to the legs of dogs shocked by venous occlusion in an attempt to prevent local fluid loss, but were unable to reduce the mortality of the procedure in this way.

*From the Department of Physiology, McGill University.

†Joseph Morley Drake Professor of Physiology, McGill University, Faculty of Medicine.

Haist and Hamilton⁶² found that by reclamping the legs of animals shocked by the tourniquet method before the stage of irreversibility had set in, it was possible to produce recovery despite the fact that all or nearly all the fluid loss into the traumatized leg had already occurred. Green and co-workers⁶³ found that fatal shock could be produced by the tourniquet method in fully anesthetized dogs with a fluid loss of an average of 18 cc per kilogram — appreciably less than the fatal hemorrhage volume, which amounts to 50 cc per kilogram or more. These workers concluded that although the initial fall of arterial pressure of dogs traumatized by this procedure is induced principally by a combination of reactive vasodilatation in the traumatized legs and initial rapid loss of body fluid into the traumatized tissues, the continuing steady decline of arterial pressure is probably due to a continuing smaller loss of fluid into the traumatized tissues, as well as to the onset of a vicious circle whereby the reduced systemic blood flow results in widespread damage to the vascular system and perhaps also to other tissues.⁶⁴

An attractive concept of the vascular changes by which this vicious circle is introduced is afforded by the recent studies of Chambers and his associates,⁶⁵⁻⁶⁸ who studied, in the mesenteries of various animals, the response of the small blood vessels to hemorrhage and trauma. Following hemorrhage or trauma there is a marked increase in the activity of the small arterioles and metarterioles characterized by marked vasoconstriction of the vessels and increase in the rate of their rhythmic dilatations and constriction that these authors call vasomotion, as well as such an increase in the sensitivity to adrenalin that complete local shutdowns of circulation may take place on injection of a 1:60,000,000 solution of adrenalin. Because of precapillary constriction, capillary flow is restricted to central channels. Flow through the open capillaries is nevertheless rapid and unidirectional. During the next reversible stage of low blood pressure, vasomotion diminishes and the contractile phase becomes progressively shorter. The response to adrenalin falls toward normal. There is a marked slowing of the flow in the capillaries and an increase in the number of capillaries having a blood flow because of the diminished vasomotion. Venules begin to dilate, and the venous flow is sluggish. Finally the hyporeactive stage is reached in which vasomotion ceases in dilatation. The response to adrenalin is greatly reduced, only a fleeting response occurring to the injection of a 1:2,000,000 solution of adrenalin. The arterioles begin to dilate, stagnation of blood occurs in the many open capillaries and venules and venular capillaries become distended by back flow. When this stage is reached, further transfusion is without effect and the transfused blood is trapped along with much of the other blood in widely dilated stagnant capillaries. According to these authors, therefore, the essential factor in the change to the irreversible stage is the loss of tone and the

development of irresponsiveness in the small peripheral blood vessels that so reduces the effective circulating blood volume that the blood pressure can no longer be maintained. Fine and Seligman⁶⁹ came to much the same conclusion from the study of the distribution of radioactive proteins introduced into the blood stream in hemorrhagic shock.

In explaining the mechanism of these changes in small peripheral vessels, which appear to lie at the root of the problem, a good case can be made out for the action of local tissue anoxia. It is clear from the work of Chambers and his co-workers that blood flow in the viscera must be markedly reduced in all stages of shock and that this is apparently even more pronounced in the peripheral system. Thus, Levinson and Essex,⁷⁰ among others, have studied the response of the ear vessels of rabbits through transparent chambers inserted in the ears of animals in traumatic shock. They noted that, as the period of onset of shock approached, there were phases when the blood flow in the chamber was shut off through arteriolar constriction. The effect of such vasoconstriction is, of course, to reduce markedly the blood flow in many organs of the body. Dole et al.⁷¹ estimated renal blood flow in dogs by means of para-aminohippuric acid and creatinine excretion rates and found the blood flow ranging from 4.6 to 12.0 liters per minute per kilogram of kidney in normal animals before hemorrhage, after hemorrhage the blood flow ranged from 0 to 3.84 liters per minute per kilogram. The latter figure was obtained in an animal having a blood flow of 6.72 liters at a blood pressure of 138 mm of mercury, and the value of 3.84 liters was obtained on reduction of the blood pressure by hemorrhage to 120 mm. In consequence, there is a greater extraction of oxygen from what blood does flow through most organs of the body, and venous blood returns to the heart with much less than its normal content of blood.⁷²

From the work of Shorr, Zweifach and Furchgott,⁷³ however, it appears that the depression of peripheral blood vessels is produced by the action of a humoral substance referred to by them as VDM (vasodepressor material), which is elaborated by skeletal muscles and by the liver. The material is apparently formed by muscles in small quantities in the compensatory stages of shock, but not by the liver at this time, nor does it appear in the blood stream of animals in the preirreversible stages, when the liver is capable of destroying or inactivating the material. With the onset of irreversibility, the liver not only fails to protect the circulation against the larger quantities of VDM that escape from skeletal muscles but also contributes significant quantities of the material itself. The cause of this change in liver function is the failure of the oxygen supply to that organ.

The liver is unique among the organs of the body in receiving the larger part of its oxygen supply from the venous system. McMichael⁷⁴ found that in the

cat about two thirds of the oxygen supply of the liver comes from the portal vein under normal conditions of blood pressure. The oxygen content of the hepatic vein is always less than that of the portal vein, and obstruction of the portal vein to a lobe causes central degeneration in its lobules. Naturally, then, the liver is especially vulnerable to the great reduction in the oxygen content of venous blood that occurs in the compensation state of shock, and in the experiments of McMichael the average saturation of portal venous blood fell from 50 per cent when the mean arterial pressure was 180 mm of mercury to only 25 per cent when, because of hemorrhage, the mean arterial blood pressure fell to 90 mm. It is now known that this deficiency of oxygen causes a number of changes in liver function. The liver loses its ability to store glycogen,⁶² and the rate of replacement of plasma protein after hemorrhage is diminished.^{75, 76} Thus, a normal unanesthetized dog not in shock replaces from 10 to 29 per cent of its total prehemorrhage plasma proteins within twelve hours after the hemorrhage, or a total weight of from 6 to 15 gm, whereas dogs in shock replace only about a tenth of this amount in the same time. Amino acids increase in concentration in the blood owing to an increased production due to protein breakdown in peripheral tissue, either because of direct trauma or because of anoxia and because the damaged liver can no longer readily deaminate them.^{77, 78} Disturbance of carbohydrate metabolism can be seen in the increase in the level of lactic and pyruvic acid in the blood,⁷⁹ and the oxygen consumption of liver slices falls off. Whereas liver slices from normal animals consume an average of 5.6 cu. mm for each milligram of initial dry weight of tissue per hour, the liver from animals in a fair state after hemorrhage consumes but 3.6 cu. mm and that from animals in a poor state only 1.82 cu. mm. It should be noted that in rats, especially those recently fed, the effects of shock on the liver are not so marked as those in fasted rats, and in fact in fed rats the liver is also apparently more resistant to anoxia.⁸⁰ The liver also loses approximately 10 to 25 per cent of its total potassium content during the course of shock or anoxia.⁸¹

As might be expected, the inhalation of pure oxygen in hemorrhagic shock is not of great assistance in improving the situation so far as the liver is concerned, inasmuch as the arterial blood saturation does not fall markedly during the critical preshock stage and the anoxia of the liver depends rather on the increased extraction of oxygen in the face of a diminished blood flow. Wood, Mason and Blalock,⁸² however, report experiments in hemorrhagic shock in dogs in which inhalation of pure oxygen increased the content of portal venous blood from 12.52 to 15.21 vol per cent. Frank, Seligman and Fine⁸³ shocked dogs by hemorrhage and continued low blood pressures for approximately two to four hours. Animals that were then perfused by exchange circulation with donor animals in which arterial blood

from the donor entered the jugular vein were not helped by the procedure, and nearly all died. On the other hand, cross circulation in the same way, except that the arterial blood of the donor entered the shocked animal through the splenic vein and therefore added arterial blood to the portal circulation, made it possible for 11 of 12 animals thus treated to survive. It is obvious that preservation of liver function is of crucial importance in recovery from advanced hemorrhagic and other types of shock and that the essential factor is the maintenance of an adequate oxygen supply to the liver.

Apart from the apparently physiologic V.D.M., bacterial toxin must also be considered, at least in experimental shock. Aub and co-workers⁸⁴ found toxin due to the presence of a *Clostridium* exotoxin in 28 per cent of experiments in which fluid was collected from traumatized muscles and injected into normal dogs. Prinzmetal, Freed and Kruger⁸⁵ found that shock was produced in 9 of 12 dogs when the quadriceps muscle was removed with aseptic precaution, crushed and replaced. When the muscle was removed and replaced without crushing, shock was not produced. If bacterial growth was prevented by appropriate bacteriostatic agents, shock did not occur. It is also apparent that damaged muscles lose potassium in large quantities and that in appropriate circumstances, more particularly when kidney function is suppressed, this ion may have a toxic effect.⁸⁶⁻⁹⁰ Bacterial toxin, but not potassium, might account for the shock reported in normal animals that are cross-perfused with animals in shock from application of tourniquets.⁹¹ In hemorrhagic shock Frank, Seligman and Fine⁸³ failed to find signs of shock in the normal animal used for cross circulation with a shocked animal.

From all this material it is possible to put forward the following view of the events that transpire in the course of hemorrhagic or traumatic shock. A reduction in effective blood volume through hemorrhage or through vasodilatation and loss of plasma in damaged regions occurs. Compensation for the diminished blood volume takes place by means of increased arterial or venous constriction, — at least in part on a sympathetic basis,⁹² — and an increased vasomotor activity in the metarterioles and precapillaries is due to the production of a vasoexcitator substance from the kidney⁷³ that may be the same as the renal hypertensive material liberated as the result of renal ischemia — it is known that the kidney removes only a small proportion of the oxygen from the blood that circulates through it, and even when blood flow is markedly reduced, it is not able to increase its utilization.^{71, 93} There is also some evidence that the vasoconstrictor substances are produced in shock even in the absence of the kidneys.⁹⁴ If, as a result of these compensatory measures, peripheral blood flow is excessively curtailed, the oxygen content of the portal venous blood becomes dangerously low, and the liver begins to suffer from

anoxia. It therefore fails to destroy the relatively small quantities of VDM produced by the damaged or partially anoxic tissues and, in addition, produces VDM itself. This material, which acts on the peripheral vessels to cause vasodilatation and stagnation of blood in an increased number of open capillaries, thus further reduces effective blood volume and sets up a vicious circle of lowered blood pressure, further tissue and hepatic anoxia and, as a consequence, further release of VDM.

THE ARTIFICIAL KIDNEY

The results of animal experimentation have for some time held out the promise that uremia and anuria in man might be treated by the removal of the abnormal accumulation of metabolic products by their dialysis through the membranes of artificial kidneys or through natural membranes, such as the peritoneum⁹⁵⁻⁹⁸. These attempts stem directly or indirectly from the work of Abel and his associates⁹⁹⁻¹⁰¹ in the years preceding World War I. The general concept of finding some substitute for impaired renal function is, of course, of much earlier origin. Thus, Abel recognized his predecessors in the method, to which he gave the name plasmapheresis, in which blood was drawn from nephrectomized animals, centrifuged and separated from the plasma and the washed corpuscles returned to the animal in Locke's solution. Other less direct methods have also been suggested, as well as the method of cross circulation with an animal with normal kidneys proposed by Nyiri¹⁰² from consideration of the fact that in parabiotic animals — that is, surgically created Siamese twins in which vascular intercommunication has been established across the communicating bridge of tissue — a single kidney may be sufficient for the excretory processes of both animals. Nyiri performed two successful experiments in one the donor dog was nephrectomized and in the other the dog was rendered uremic by uranium poisoning. In both the nonprotein nitrogen of the donor dog fell, whereas that of the recipient rose, only to be excreted without damage to the normal animal. Other experiments failed, however, because of clotting in the communicating tubes. With the introduction of more active preparations of heparin this difficulty was overcome, and Thalheimer^{103,104} was able to simplify the technical problems by the method of exchange transfusions. By this method approximately 200 cc of blood was exchanged between an anuric and a normal dog and the process repeated twenty to forty times. Thus, in one experiment, the nonprotein nitrogen of the anuric animal fell from 75 to 61 mg per 100 cc after twenty exchanges and to 54 mg after forty. At the same time, the nonprotein nitrogen concentration of the normal dog rose from 22.5 to 36.5 mg per 100 cc, but this was excreted in a short time without harming the animal.

The method of Abel, Rowntree and Turner,⁹⁹ however, envisaged the utilization of an artificial mem-

brane constructed of collodion tubes through which arterial blood flowed only to return to the animal through an appropriate vein. The dialyzing tubes were then immersed in a fluid bath, in which substances might diffuse from the blood, and the diffusion of the substances out of the blood could then be regulated by variation in the composition of this fluid. If the fluid was of the same composition as normal plasma, the apparatus could be expected to remove only abnormal constituents or normal constituents present in abnormal concentration. The authors made the following observations:

Any constituent of the blood which it is desired to retain in the animal's system may be prevented from dialyzing out by the addition of the proper amount to the outer fluid. Where the object of the experiment is merely to remove from the blood abnormal constituents, as e.g., poisons, or constituents specifically secreted into the blood by a certain organ, normal serum from a similar animal may be used, thus insuring complete balance of all normal constituents, inside and out.

Hirudin prepared from the heads of leeches was used as an anticoagulant. There was a considerable fall in blood pressure when the apparatus was put into operation when a dog weighing 5.8 kg was connected to a dialyzer consisting of sixteen tubes each 20 cm long and 8 mm in diameter, the apparatus containing in all 200 cc, the arterial blood pressure (presumably, the mean pressure) fell from 120 mm of mercury to 64 mm. Lung edema was noted in some experiments. The method was used to collect various normal and abnormal material from the blood, and it was shown that nonprotein nitrogen constituents appeared in the dialysate in approximately the proportions in which they existed in the blood. It was, however, apparently Necheles^{105,106} who first used the method to reduce the nonprotein nitrogen of nephrectomized dogs. In two experiments the nonprotein nitrogen was reduced from 122 to 101 and from 218 to 161 mg per 100 cc, respectively, by several hours' diffusion through a dialyzing apparatus constructed of ten tubes of gold-beater skin having a total area of approximately 4000 sq cm. Apparently, Haas^{107,108} also had success in the dialysis of blood in living dogs with a collodion-tube apparatus patterned after Abel's, but had difficulty owing to the toxicity of the hirudin he employed. When he was able to obtain less toxic preparations of this anticoagulant, further experiments on dogs were carried out and a single short experiment was tried in man, a relatively short tube system being used. In the fifteen minutes of the experiment an indican clearance of 150 cc was established.

The successful application of this technic in man was made possible by the development of heparin and of cellophane from which a dialyzing tube 23 mm wide and about 45 meters long was constructed by Kolff and Berk^{96,98}. Through this tube blood was transported in small quantities at a time to ensure spreading over a large surface and thus increas-

ing the rate of dialysis. Blood was dialyzed against a solution containing 0.6 per cent sodium chloride, 0.2 per cent sodium bicarbonate, 0.04 per cent potassium chloride and 0.5 to 2.0 per cent glucose. In the absence of calcium from the dialyzing solution this ion was lost from the blood and was replaced by intravenous injection of calcium gluconate. In trials of the apparatus in patients suffering from anuria it was possible to remove large quantities of nonprotein nitrogenous material from the blood, and it appears that in the second case, as reported by Snapper,⁹⁵ the life of the patient was in fact saved. On the eighth day of anuria the blood urea nitrogen was 184 mg and the serum potassium 55 mg per 100 cc, the patient was comatose, and there was edema of the buttocks and legs. Dialysis through the artificial kidney was carried out for eleven and a half hours, during which 80 liters of blood was circulated through the apparatus and 60 gm of urea removed. The blood urea nitrogen fell to 57 mg and the serum potassium to 19 mg per 100 cc. It is apparent that at a serum potassium level of 55 mg per 100 cc the lethal limits had practically been reached and death was to be expected at any time. Death from this cause being averted by the removal of the excess potassium, the patient's life was preserved for another day, and by that time renal function had begun to reappear and the patient recovered.

Impressed by the difficulties with clotting encountered by workers in the preheparin days, Ganter¹⁰⁹ employed the peritoneum itself as a dialyzing membrane, he reported a case of uremia with pleural effusion in which replacement of 750 cc of pleural fluid by saline was followed by clinical improvement. He also successfully reduced the nonprotein nitrogen of anuric guinea pigs and rabbits by intraperitoneal lavage with saline. Rosenak and Siwon¹¹⁰ then suggested a constant intraperitoneal perfusion at the rate of 1 to 4 liters per hour, believing that the rate of diffusion of materials into the perfusing solution would be more rapid if it were constantly refreshed with new fluid. Since that time practically all workers have employed the constant-drip method, although it is clear from the work of Darrow and his associates¹¹¹ that fluid left in the peritoneal cavity rapidly comes into equilibrium with blood and that the nonprotein nitrogen content of this fluid equals that of blood within fifteen to twenty minutes. Although it was apparent from these and other investigations¹¹²⁻¹¹⁴ that the method might temporarily reduce the nonprotein nitrogen and diminish the symptoms of uremia, there was little evidence that the life of the uremic animal could thereby be prolonged, and it is apparent that infection posed a considerable problem. The method was nevertheless employed in man by Balázs and Rosenak,¹¹⁵ who perfused the peritoneal cavity of 2 patients suffering from uremia consequent to mercury poisoning with 12 liters of fluid. In the first case, in which the patient was

perfused for half an hour with a 4.2 per cent dextrose solution, the nonprotein nitrogen fell from 184 to 158 mg per 100 cc, whereas in the second case, after perfusion for an hour and a half with 19 liters of an 0.8 per cent sodium chloride solution, the nonprotein nitrogen fell from 149 to 139 mg per 100 cc. By the introduction of a rigid aseptic technic assisted by the use of penicillin and sulfadiazine, Seligman, Frank and Fine¹¹⁶ were able to prolong the period of dialysis to permit nearly continuous irrigation for twenty-four to thirty-six hours at a full rate of 25 to 35 cc per minute and thereby to control uremic symptoms effectively and to produce marked reduction in blood urea concentration in dogs rendered anuric by bilateral nephrectomy. Once the nonprotein nitrogen was lowered to more normal concentrations, shorter periods of dialysis (from eight to ten hours) carried out once in every twenty-four hours proved sufficient to maintain the animal, and it is clear that life in these animals was prolonged for from three to ten days. Abbott and Shea¹¹⁷ report an animal kept alive for nine days after bilateral nephrectomy, which also represents a clear prolongation of the survival period. Finally, the Boston workers have reported the successful treatment of uremia following sulfadiazine therapy in which the therapy was begun after eight days of almost complete anuria. After four days of perfusion, the blood urea concentration fell from 72.7 to 37.8 mg per 100 cc. Clinical improvement was noted, and on the fourth day urine flow began again. The daily urea output by peritoneal drainage varied from 12 to 20 gm per day, and the blood urea clearance averaged nearly 15 cc of blood per minute. Despite extreme care and the liberal use of penicillin, signs of peritoneal infection appeared but did not interfere with the successful treatment of the patient.

TREATMENT OF DEHYDRATION IN INFANTS

In a previous report in this series,⁸⁶ attention was called to the fact that in cases of water deprivation or loss of body fluid there is an extra secretion of potassium unassociated with nitrogen loss in the urine. By the excretion of such potassium in a higher concentration in urine than it was found in cell water, the body was able to retain cell water in the plasma and thus to mitigate the loss of extracellular fluid. The pediatricians were among the first to note this phenomenon, which was reported by Gamble and co-workers¹¹⁸⁻¹¹⁹ in fasting diabetic children and in diarrheal disease in children. Darrow¹²⁰ has recently estimated the amount of intracellular potassium lost in cases of severe dehydration due to diarrhea in infants and has found cases in which the total loss of intracellular potassium amounted to approximately one fourth of the estimated normal potassium content of the body.

It is known that a deficiency of potassium is not without harmful effects, the paralysis of familial periodic paralysis is one such condition, and muscular

weakness may be produced in man and experimental animals when potassium is excessively low. More important, a low potassium level is associated with the development of heart failure, with recovery when adequate potassium is administered, and both muscular and myocardial weakness have been noted in infants suffering from the dehydration of diarrhea. These facts and the general consideration that replacement therapy ought on theoretical grounds to be complete have led Govan and Darrow¹²¹ to use potassium in the treatment of the dehydration of diarrhea in infants. After the initial treatment of shock, replacement of fluid was effected during the first twenty-four hours by parenteral administration of from 80 to 150 cc per kilogram of body weight of a mixture of potassium chloride, sodium chloride and sodium lactate. After the first day smaller amounts (20 to 50 cc per kilogram of body weight) were given daily so long as the stools remained watery. In some cases from 1 to 2 gm of potassium chloride was added to each day's feeding when oral feeding was begun. The new method of treatment was instituted in September, during the preceding two months 53 patients had been treated by the conventional method, and 17 had died. During September and October, 50 patients were treated by the new method, and only 3 died. In general, the potassium therapy did not shorten the period of diarrhea, but it did enable the infants to withstand a disease that would otherwise have been fatal.

The most significant complication of the treatment may prove to be potassium intoxication. Many patients are presented in a state of shock after a considerable period of illness. In such circumstances the combination of tissue anoxia and low renal output may lead to the development of deceptively high concentrations of potassium within the serum. The immediate administration of potassium-enriched fluids to such patients may be dangerous, as was shown in the case of potassium intoxication reported by Govan and Weiseth¹²² in which a serum potassium level of 12.3 milliequiv per liter was noted and the typical, premortal, intraventricular block developed. Fortunately, the condition was recognized, and recovery was complete after the administration of 15 cc of calcium gluconate and 150 cc of hypertonic glucose solution. It has therefore been suggested that in the period of shock in moribund patients and perhaps in all cases of severe diarrhea, infusions of physiologic saline and glucose solution should be initiated for an hour or until urine formation is assured, after which the solution containing potassium chloride can be started. So characteristic are the electrocardiographic signs of potassium intoxication that this instrument, in combination with a cardioscope, or one of the modern visual writing instruments, might well be employed as a constant check on the rate and quantity of potassium infusion.

SPLenic HORMONE CONTROL OF PLATELET FORMATION

Although it seems well established from the work of Taylor and others described in an earlier report in this series¹²³ that platelets play no great part in the primary mechanisms responsible for blood clotting, it is equally obvious that they are important in causing clot retraction and in sealing off injured capillaries after damage. Whatever their specific function may be, bleeding takes place when they are excessively reduced in the blood stream, and a dramatic increase in the number of platelets occurs along with cessation of symptoms when the spleen is removed. A paper by Dameshek and Miller¹²⁴ provides the major outline of an acceptable theory of platelet regulation. Studying the megakaryocytes of sternal bone-marrow punctures in 10 patients with normal hematologic findings, they established a normal megakaryocyte count of not more than 300 per million nucleated cells. About two thirds of these megakaryocytes contained platelets or platelet-like bodies at the periphery of the cytoplasm and were apparently actively producing platelets. Differential counts of megakaryocytes were made in 5 cases of acute idiopathic thrombocytopenic purpura before splenectomy, and it was found that the number of megakaryocytes per million nucleated blood cells was on the average three times greater than that in normal subjects and only about 14 per cent of the megakaryocytes showed obvious platelet production. Following splenectomy, the number of platelets became sharply increased and approximately 73 per cent of megakaryocytes showed platelet production. Huge masses of platelets were seen extruding from previously unproductive megakaryocytes, and these also occupied large parts of the microscopic field.

The hormonal nature of the influence exerted by the spleen on platelet production was suggested as early as 1915 by Frank, who with Mines, in 1917, held the belief that the material was a toxic substance.¹²⁴ In 1938 Troland and Lee¹²⁵ described the extraction, from the spleens of patients suffering from idiopathic thrombocytopenic purpura, of a material that reduced the number of platelets in the circulating blood of rabbits, cats, dogs and monkeys when injected in fairly large amounts. Since that time the observation has been confirmed by a number of other investigators, but not by all.¹²⁶⁻¹³¹ The concept held by Dameshek and Miller¹²⁴ regarding the pathogenesis of the disease is that it is due fundamentally to an abnormality of the spleen that exerts an unusual effect on the production of platelets from megakaryocytes in the bone marrow by arresting the maturation of megakaryocytes. They postulate a hormonal relation between the spleen and the bone marrow and describe the condition as hypersplenism or hypersplenic thrombocytopenia.

This implies that the spleen normally regulates the maturation of megakaryocytes by the release of smaller quantities of its hormone, and Dameshek and Miller point to the persistently high platelet level that may be present for long periods after removal of a normal spleen. They also point to the association of thrombocytopenia with other conditions in which splenomegaly occurs. Although Dameshek and Miller have confirmed the presence of a platelet-reducing substance in extracts of spleens from cases of idiopathic thrombocytopenic purpura, the final link in the chain of evidence requires to be forged — namely, the unequivocal demonstration that an extract of normal spleen can cause a fall in platelet count. The hormonal studies also need to be controlled by means of bone-marrow punctures to demonstrate that the reduction of thrombocytes following injection of extract results from the arrest of megakaryocytic delivery of thrombocytes and not from nonspecific toxic action on the platelets themselves. Some observers have noted that, following reduction of thrombocytes by injection of extracts, there is occasionally a temporary thrombocytosis in the recovery phase. This suggests that failure of platelet delivery is in fact involved and that once the barriers to delivery are removed, the platelets again flood into the blood stream.

PITUITARY-ADRENAL HORMONAL CONTROL OF LYMPHOCYTES

The nature of the hormonal regulation of another formed element of the blood, the lymphocyte, together with the physiologic significance of the reaction, has recently been elucidated through the work of White and Dougherty,¹³²⁻¹³⁶ reviewed recently by Cope and Rosenfeld.¹³⁷ According to these investigators the influence of the adrenal cortex on lymphoid tissue was first noted by Addison, who observed hyperplasia of this tissue in the disease that bears his name. Lymphoid-tissue hyperplasia is also found in experimental animals after adrenalectomy, whereas adrenocortical hypertrophy and injection of adrenocortical hormone cause involution of the thymus and other lymphoid tissue. These adrenocortical effects are in turn under control by the pituitary gland, for injection of pituitary adrenotropic hormone produces a profound lymphopenia that does not appear if the pituitary hormone is given to adrenalectomized animals. Only compounds of the adrenal cortex that have a gluconeogenic function (compound E of Kendall) induce lymphopenia, which results from the failure of delivery of lymphocytes into the circulation because of profound degenerative changes taking place in lymphoid tissue. These changes were found within an hour after the injection of either adrenotropic or adrenocortical hormone and persisted for as long as six hours. They were characterized by pyknosis of medium-size and small lymphocytes, the shedding of the cytoplasm of lymphocytes, a decreased number

of lymphocytes in the lymphoid tissue and extreme edema of all lymphatic structures studied. During this period mitosis ceased. Concomitantly, there was an increase in the serum protein associated with the gamma globulin fraction and an increase in circulating antibodies. From this time relation among histologic changes in lymphoid tissue, blood lymphocyte levels, serum protein concentrations and antibody titers, the authors concluded that a portion of the increased serum protein is antibody globulin derived from lymphocyte dissolution. This mechanism is shown by the authors to account for the so-called "anamnesic response" — that is, the enhancement of antibody titers in the serums of previously immunized animals by a wide variety of unrelated stimuli, as well as by such toxic substances as benzene and potassium arsenite.

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE COUNCIL

Special Meeting, October 2, 1946

A STATED meeting of the Council was called to order by the president, Dr Dwight O'Hara, Middlesex South, on Wednesday, October 2, 1946, at 10.30 a.m. in John Ware Hall, 8 Fenway, Boston. Two hundred councilors (Appendix No. 1) were present.

In opening the meeting the President read the following obituaries:

CHARLES SUMNER ADAMS — Dr Adams was born at Carlisle on October 12, 1869. He was educated at the Howe School in Billerica and at Berwick Academy. He graduated from the Harvard Medical School in 1894 and settled in Quincy the same year. In 1900 he married Frances Gertrude Monahan, who survives him, with two daughters.

Dr Adams served as vice-president of the Norfolk South District Medical Society in 1911 and 1912, and as president in 1913 and 1914. Thereafter he was continuously in the service of the Society until his death. He was alternate nominating councilor for eight years, nominating councilor for two years, councilor for twenty-one years and supervising censor for twenty-one years. His death was said to be due to carcinoma of the intestine.

HENRY MAYOR LANDESMAN — Dr Landesman was born in 1884 and graduated from the College of Physicians and Surgeons in Boston in 1917, being licensed to practice the same year in Massachusetts. He was a councilor for the Norfolk District Medical Society from 1935 to 1940 and from 1944 until his death. Between 1937 and 1944 he served as secretary of the Committee on Automobile Insurance Claims. He was sixty-one years of age at the time of his death.

WILLIAM D'ARCY KINNEY — Dr Kinney was born in 1873 and received his medical degree from Bowdoin Medical School in 1899. He had practiced in Osterville for nearly half a century. He was president of the Barnstable District Medical Society from 1913 to 1915, commissioner of trials from 1915 to 1919 and a censor in 1912 and 1913 and from 1916 to 1919. He was a supervising censor from 1922 to 1946 and a member of the Council from 1919 to 1946. He was a member of the Nominating Committee from 1922 to 1946, a member of the Executive Committee of the Council from 1941 to 1945, an alternate member in 1945 and 1946, a member of the Committee on Public Relations from 1942 to 1946 and representative to the Massachusetts Central Health Council from 1930 to 1946. Dr Kinney was associate medical examiner for Barnstable County for a period of about twenty years. His widow and a son survive him.

Although Dr Kinney was not actually a member of the Council at the time of his death on July 12, he had been active in its affairs for nearly thirty years and he will be widely recalled as an unusually faithful, interested and helpful fellow of the Massachusetts Medical Society.

WALTER HALL PULSIFER — Dr Pulsifer of Whitman, died on September 26. He was born in 1883. He graduated from Tufts College Medical School in 1908 and joined the Massachusetts Medical Society in 1910. Throughout his professional life he was especially interested in pediatrics. Dr Pulsifer was a censor from 1926 to 1927 and again in 1929. He was commissioner of trials for the years 1930 and 1931, a councilor and a member of the Nominating Committee from 1937 to 1944, inclusive, and during 1944 was a member of the special committee that was asked to look into the possibility of better publicity for the Massachusetts Medical Society. In 1945, Dr Pulsifer

was elected vice-president of the Plymouth District Medical Society and this year was elected president of that district society, holding this important office, and by virtue of it being a vice-president of the Massachusetts Medical Society, at the time of his death.

At the request of the President, the Council stood for one minute in silent tribute to the memory of these deceased councilors.

The Secretary submitted the record of the annual meeting of the Council held on May 21, 1946, as published in the *New England Journal of Medicine*, issue of September 12, 1946, and moved its adoption. This motion was seconded by Dr John Homans, Suffolk, and it was so ordered by vote of the Council.

REPORTS OF COMMITTEES

Executive Committee — Dr Michael A. Tighe, Middlesex North, secretary.

The Secretary submitted this report, which is as follows, as published in the "Circular of Advance Information" and moved its acceptance.

The Executive Committee of the Council held its pre-Council meeting on September 4, 1946, at 4:00 p.m., at 8 Fenway, Boston. The committee processed the following committee reports:

Committee on Arrangements

The Executive Committee noted that this report contains two recommendations that the annual meeting be held in Boston on May 20, 21 and 22, 1947, and that the meeting be increased in length from two and a half to three days.

The Executive Committee recommends that the Council adopt these recommendations.

Committee on Legislation

The Executive Committee, in recommending the acceptance of this report, notes that it is primarily one of information. It contains no recommendations.

The Executive Committee would particularly direct the attention of the Council to that part of the report which indicates that the members of the General Court are becoming increasingly co-operative with the Massachusetts Medical Society in its efforts toward maintaining high standards of medical practice in the Commonwealth. It further notes that this report gives much of the credit for this state of affairs to Mr. Charles Dunn, legislative counsel. The Executive Committee would include in this same category the chairman, the members of the committee and all those who have extended much well directed effort toward this same end.

Committee on Public Relations

The Executive Committee regards this report as largely informational. It notes, however, a few lines that are in the character of a recommendation. This recommendation would refer to the Massachusetts Hospital Association certain financial difficulties which have arisen between hospitals and insurance companies. This matter came originally to the Council's attention by means of certain

issue a questionnaire to every member of the Society based on the wishes of the Council

It was pointed out that this questionnaire would go only to members of the Society, not because there was any desire to exclude others from this program but because there was no other list of physicians available

The Executive Committee next turned its attention to the third question which the committee propounded "What formula shall be used whereby the fees paid to the specialist shall be differentiated from those paid to the general practitioner?" The suggestion of the committee presenting this report is that the schedule of fees adopted by the Council on April 10, 1946 be regarded as specialists' fees and that when the services called for in this schedule are rendered by general practitioners the compensation shall be 20 per cent less than that set forth in the schedule

The Executive Committee recommends that the Council adopt this formula. The Executive Committee notes that the committee asks for a leeway not to exceed 5 per cent, so the fees finally set down for the general practitioner may appear in round numbers

The Executive Committee also recommends that the Council adopt this proposal

The report speaks of the action of the Council on April 10, 1946, whereby the Blue Shield was designated as the administrative agent for this veterans' medical-care plan in Massachusetts. The committee now recommends that this action be rescinded

It was explained that the Medical Service Administration of New Jersey operated a medical-care plan for the veterans identical with that adopted by the Council on April 10 and that New Jersey's experience with this plan was rather distressing

This experience can best be stated by reading into this record a letter received from Dr. Norman M. Scott, medical director of the New Jersey plan, by the Secretary

July 25 1946

Dear Dr. Tighe

This will acknowledge receipt of your letter dated July 15 relative to care of the veteran

I almost hesitate to write of our experience for fear of being misunderstood

The Medical Society of New Jersey, and the physicians of New Jersey as a whole are anxious to fulfill any obligation they have toward the veteran in the care of his service connected disabilities. The problem reduces itself to definition of the obligation of the profession and the means of fulfilling this obligation

The Society has organized two nonprofit medical service corporations: Medical Service Administration of New Jersey and Medical-Surgical Plan of New Jersey

You are probably acquainted with Medical Surgical Plan. It operates on the prepayment insurance basis providing benefits for services of private physicians rendered its subscribers who are admitted to hospital for treatment. It is similar to Massachusetts Medical Service

Medical Service Administration deals with problems of the indigent and low income group and plans which co-operate with local and federal government agencies such as the Farm Security Administration Medical Plan and the City of Newark Medical Plan for care of the indigent and medically indigent of the city. It is a small administrative organization. It appeared to be the logical agency in New Jersey to deal with the veterans problem. In fact we could not use our larger organization, Medical-Surgical Plan, because of the chance of jeopardizing the subscription funds of our subscribers.

In February 1946 Medical Service Administration entered into what we considered a very simple contract with V. A. We agreed that all authorizations for medical care of the veteran would be issued through our office that physicians' reports would be returned through our office and that we would bill the V. A. at intervals for authorized services rendered. We had special agreements with our 3000 physicians to render the services and a fee schedule acceptable to the majority of physicians. The Society advanced us \$10,000 to place the plan in operation

We operated the plan until May 15 1946. Some of our difficulties were as follows:

1. The load was heavier than we had anticipated. We processed an average of 300 claims a day. The return of reports from physicians rose as high as 248 on one day. The recording of all these details in our records required a lot of detail clerical work. For instance it took the time of two clerks to open and sort the mail. Telephone messages from physicians and veterans were very heavy.

2. We developed a force of twelve typists and one male executive assistant. It is difficult to train girls to do this work and to acquaint them with such subjects as medical nomenclature and methods of properly posting medical records. These twelve girls were able to handle 300 cases a day plus the incoming reports. These 300 cases were mostly treatment cases. In addition we processed about 50 physical examination cases a day averaging 3 examinations per case. We never were able to process the full number of physical examination cases referred to us and on May 15 had a backlog of about 1000 physical examination cases unprocessed.

3. As an example one type of treatment case proved very difficult to administer. A physician in a small town would request us say eight office visits, a gastrointestinal x-ray series, blood chemical studies and a gastric analysis, or a group of similar diagnostic services in a case under his care. The authorization would be issued to us in the name of the doctor in the small town who had no facilities for rendering such services. V. A. insisted that all such authorizations be billed them as one authorization and that any part of the authorization not included in our billing be canceled. This meant that we had to issue the authorization to the small town physician have him refer the case to a proper consultant, obtain the reports of consultants and include them with his report at the end of the month. We would then bill V. A. and pay the general practitioner for all services and he in turn would pay the consultants. Physicians do not like this method it is not within the framework of private medical practice. Or we could split up the authorization in this office and distribute it to the various consultants with a notice that they return their reports to us and a copy to the general practitioner. We would then wait until all reports contained in the authorization were received in this office so we could bill V. A. under one item. The trouble with this method was that the veteran would not report for certain of the examinations or the consultant would neglect to render his report promptly and we would have to follow it up by letter or if we did bill V. A. for the reports received and later a consultant rendered a report it would not be payable as the authorization had been terminated and the item closed in the V. A. finance department when the first reports were received. It is complications such as these which give administrators gray hairs.

4. We had trouble finding sufficient office space and finally wound up with offices in three different buildings in the city.

I have outlined above a few of our difficulties. These are administrative difficulties which could have been overcome in time and were not the main reason for changing our contract.

In operating the plan we simply received authorizations from the Regional Office and retyped these authorizations on our own forms and forwarded them to the physicians designated in the authorizations. This applied to treatment authorizations. The physical examination authorizations bore no physician's name and the examinations were delegated by us to a general practitioner or specialist capable of performing the examination requested. In other words we were a fifth wheel which delayed rather than expedited the rendering of care to the veteran. We had no control over the volume of the type of care rendered or the standards of medical care except to determine that the services were rendered by fully licensed physicians. We were just repeating work already done by the Regional Office.

Billing the V. A. was a formidable effort. They must be billed in each case according to claim number of the veteran his name date of the authorization date of each service each item of service cost of each service and total. This makes a long voucher especially when done without proper equipment. Our largest voucher covering a period of two weeks was 91 pages long. These vouchers are inspected and compared with the authorizations item by item in the medical division of the V. A. Regional Office. The inspection of the 91 page voucher mentioned above consumed about eighteen days. When approved by the medical division the vouchers are forwarded to the finance division where the inspection is repeated by comparison with the copies of authorizations retained by the finance officer. Vouchers then go to the procurement division and finally are forwarded to the Treasury Department in New York for payment. The result is a delay in payment. We have been paid on one voucher covering physicians' reports received between March 15 and 0 totaling about \$700 of which our administrative allotment was \$35. This is our total income to date although we must still maintain and support a skeleton organization to complete this work at the expense of the Society. Our outstanding vouchers have a value of about \$75,000 which we know will eventually be paid, of which our administrative allotment is about \$5,500.

To have continued the plan would have cost the Society many thousands of dollars which we did not feel was warranted even though we thought there was a fair chance of being able to reimburse it at least in part.

I think there is an advantage in having a recognized agency of each state society involved in the administration of the plan. Many of the men have expressed the opinion that they would rather deal through our office than directly with the Regional Office and that they liked our administrative procedure better. It is apparently working satisfactorily in Michigan through Michigan Medical Service and in California through California Physicians Service. They are both large organizations with complete modern accounting facilities and with sufficient trained personnel to absorb the load. The setup of Massachusetts Medical Service under the able administration of Mr. Cahalane and Dr. Hayden should be able to do a much better job than we did. The men in Massachusetts would perhaps rather work through them than directly with V. A. but I still feel the work of Massachusetts Medical Service would be almost entirely limited to that of a distributing agency for V. A.

This brings me back to a denouement of the obligation of the profession to the veteran. It seems to me that if the majority of physicians agree to render service to the veteran at fees agreed on by the majority and participate conscientiously in the program we have fulfilled our obligation. It should not be necessary for the profession to assume responsibility for administrative matters. V. A. does however need our administrative assistance and advice. On this promise we changed our contract. I am enclosing a copy of the new contract and the preliminary edition of an article just dictated to appear in our August journal.

It is all a new problem a difficult problem for both V. A. and the profession. Difficult administrative problems will arise and continue to arise until the best solution of the entire problem is evolved. We are much interested in the problem and will be interested in the solution promoted by your society.

Yours very truly

[Signed] NORMAN M. SCOTT
NORMAN M. SCOTT, M.D.
Medical Director

letters which the Secretary received from Dr. Shields Warren. These letters were referred to the Committee on Public Relations at the direction of the Council.

The Executive Committee recommends the adoption of the recommendation.

Subcommittee on Labor and Industry

The Executive Committee recommends the adoption of the recommendation that this subcommittee be discontinued.

Committee on Postwar Planning

The Executive Committee notes that this report contains two recommendations.

The first is that the Council create a special committee to be known as the Committee on Emergency Medical Service. In the discussion attending this subject before the Executive Committee, it came out that this matter was originally referred by the Council to the Committee on Postwar Planning. It came to the Council's attention through a letter, which had been received from Dr. Edward Bortz, requesting the formation of a committee within the Massachusetts Medical Society, which committee would be expected to collaborate with a similar committee authorized by the House of Delegates of the American Medical Association and headed by Dr. Bortz. The purpose was to study the medical resources of the country and how best to mobilize them in times of war or other disaster.

The Executive Committee noted in connection with this recommendation that the Postwar Planning Committee expressed its belief that, in the naming of the personnel of such a committee, attention should be paid to utilizing the experience gained in the last world war to the end that such mistakes as were made in that war might not be repeated.

It also came out in the discussion that, because the Postwar Planning Committee envisioned a time when its job would be finished whereas the work of the proposed committee might go on for many years, it would be better to handle this matter through a committee set up for this special purpose.

The Executive Committee recommends the adoption of this recommendation.

The second recommendation calls on the Council to approve of the inclusion in the program of the annual meeting in 1947 adequate discussion of some topic in medical economics.

The Executive Committee approves of this recommendation and, if adopted by the Council, recommends that the matter be referred to the Committee on Arrangements.

Committee Appointed to Make a Survey of Malpractice Insurance in Massachusetts

The Executive Committee recognizes that this report is purely informational. It speaks of the study which is being conducted by this committee and of some of the things which this study is turning up. The report offers no recommendation. The committee proposes to continue the study of this important study. It will offer its recommendations to the Council at a later date.

The Executive Committee recommends that the Council accept this report as one of progress.

Medical Advisory Committee to Regional O.P.A.

This report is purely informational. It contains no recommendation. The Executive Committee recommends that it be accepted by the Council.

Committee Appointed to Meet with General Hawley with a View of Formulating a Program in Massachusetts for the Medical Care of Veterans and Their Dependents

This report indicates that if the Society is to co-operate with the Veterans Administration in this program, the Council must differentiate between the specialist and the nonspecialist, something the Society has never done before.

The committee seems fully aware of the seriousness of this problem and rightfully does not assume the responsibility for its solution.

The committee submits three questions to the Council, all of which must be answered if it is to proceed.

The Executive Committee recommends that the Council answer the first question "Shall such a differentiation be made?" in the affirmative.

With regard to the second question "How shall it be arrived at?" the Executive Committee notes that the committee offers two suggestions, the first of which would allow the individual doctor to state in which one of these two groups he should be placed. The Executive Committee notes that the report says that this is the method pursued by the New Jersey Medical Society.

In this connection there was read into the record of the meeting of the Executive Committee the following questionnaire which was sent to the members of the New Jersey Medical Society:

- | | | |
|---|--------------------------------------------------------------------------------------------------------------------------------------------|---------------------------|
| 1 | I agree to participate in the Veterans Medical Care Plan as arranged between the Medical Society of New Jersey and Veterans Administration | |
| 2 | I am in general practice | |
| 3 | I am doing special work in | |
| 4 | I am confining my work entirely to | |
| 5 | I can accommodate | physical examinations per |
| | month in my office | M.D. |

The debate on this particular suggestion indicated that it left too much latitude in the hands of the individual doctor which might, however, be somewhat offset by reason of the fact that once the individual doctor had classified himself as a specialist in a particular field he would not be permitted to see patients under this program in any other field.

The Executive Committee recommends that the Council reject the first suggestion.

The Executive Committee recommends that the second suggestion be amended by the Council so that the comma between the words "boards" and "those" be deleted and the word "and" be inserted in its place to read:

To designate as specialists all those so certified by the specialty boards and those physicians who state that they limit their practice to a special field or who practice a specialty in an approved hospital as a member of that hospital's regular staff.

The Executive Committee recommends that the Council adopt this suggestion as amended.

In the debate leading to this action of the Executive Committee it was made clear that the Society will not be called on to designate specialists in the field of neurology or psychiatry. The debate also indicated that the Executive Committee believes that there are many individual physicians who by long practice in a special field have fully qualified themselves as specialists in that field even though they have for one reason or another never qualified before a specialty board. It was observed that there were those who might not see much difference between the first suggestion and that part of the second which allows a man to qualify by stating that he limits his practice to a specialty.

In this connection it was pointed out that, in the first, the doctor himself, without further qualification, says in which group he should be placed, while in the second he is asked to state the circumstance of his practice, his classification being made on this as a statement of fact. It was further explained that this qualification was included in the second so as to permit that individual to qualify as a specialist who, while devoting himself exclusively to a special field, was not a member of the staff of an approved hospital.

It was the general feeling in the Executive Committee that, if the Massachusetts Medical Society were to designate any physician as a specialist, it must have control of the circumstance under which such a designation would be made.

The Executive Committee believes that in the second suggestion such controls exist. There was no disposition in the Executive Committee to regard the controls set up in the second as perfect. They were the best that could be thought of at the moment. Time and experience might indicate the necessity of their modification at some future time.

It was explained by Dr. McCarthy, chairman of the committee having this matter in hand, that if the Council accepted these or other proposals this committee would

It was pointed out that, if success was to crown the Society's efforts in the continued fight against the federal control of medicine, it should join forces with all those who think as it does and whose goal is the same even though the paths by which that goal is reached may in some respects differ.

With such thoughts in mind, the Executive Committee recommends that these communications be referred to the Committee on Public Relations, with the suggestion that a subcommittee be set up by that committee for the purpose of the study outlined in them.

MICHAEL A. TIGHE, M.D., *Secretary*

The motion to accept this report was seconded by Dr. Walter G. Phippen, Essex South, and it was so ordered by vote of the Council.

Committee on Arrangements — Dr. Sidney C. Wiggin, Suffolk, *chairman*

This report, which is as follows, was submitted by the Chairman:

A meeting of the Committee on Arrangements was held on June 28, 1946. It was voted by the committee that it recommend to the Council that the annual meeting should be held in Boston on May 20, 21 and 22. Space has been reserved at the Hotel Statler for the meeting for these days.

It was also voted to recommend to the Council that the meeting be increased in length from two and a half to three days.

Dr. Wiggin moved its acceptance. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

The President called attention to the fact that this report contained two recommendations and announced that the Executive Committee had approved both of them. Dr. John J. Curley, Worcester North, moved the adoption of the recommendations. This motion was seconded by Dr. David Cheever, Suffolk, and it was so ordered by vote of the Council.

Committee on Legislation — Dr. David L. Belding, Norfolk South, *chairman*

This report (Appendix No. 2) was submitted by the Secretary in the absence of the chairman.

Dr. John J. Curley moved the acceptance of the report. This motion was seconded by Dr. Carl Barse, Norfolk, and it was so ordered by vote of the Council.

Committee on Public Relations — Dr. Albert A. Hornor, Suffolk, *secretary*

This report (Appendix No. 3) was submitted by Dr. Hornor.

The President called attention to the fact that this report contained one recommendation, namely, that certain financial difficulties which certain hospitals were having with insurance companies be referred to the Massachusetts Hospital Association as the agency more particularly concerned in this matter. Dr. Hornor moved the acceptance of the report and the adoption of the recommendation. This motion was seconded by Dr. James V. McHugh, Worcester North.

Dr. P. R. Withington, Norfolk, expressed the thought that the doctor did have a concern in this

matter inasmuch as the doctor needed the hospital quite as much as the hospital needed the doctor.

The President pointed out that this matter was fully discussed in the Committee on Public Relations and that, inasmuch as the committee was not aware of the details of this controversy, it would be much better to refer the matter to the Massachusetts Hospital Association as the organization most fitted to deal with it. The President added that the Executive Committee had approved of the recommendation. This motion was adopted by vote of the Council.

Subcommittee on Labor and Industry — Dr. Daniel B. Reardon, Norfolk South, *chairman*

The report, which was offered by the chairman, is as follows:

I have felt for some time that the Subcommittee on Labor and Industry had fulfilled its obligations and I can see no reason why it should be continued. Therefore, I recommend that this subcommittee be discontinued.

Dr. McHugh moved the acceptance of the report and the adoption of the recommendation. This motion was seconded by Dr. Phippen, and it was so ordered by vote of the Council.

Committee on Postwar Planning — Dr. Howard F. Root, Suffolk, *chairman*

This report, which is as follows, was presented by Dr. Root:

The president of the Society sent to the chairman of the Postwar Planning Committee a communication from the headquarters of the American Medical Association in June regarding the formation of a committee designed to consider the utilization of medical services in any future national emergency. The chairman of this committee is Dr. Edward Bortz, of Philadelphia. A consideration of this matter was turned over to the Subcommittee on Veterans Affairs, and as a result of their report, the committee believes that the Council should take some action in relation to this important affair. A letter from the chairman of the national committee, Dr. Bortz, states that one objective of this committee is to secure from all medical officers who served in World War II a statement regarding their assignment. The committee recommends that the Council direct the President to appoint a Committee on National Emergency Medical Service and to include in its membership sufficient representation of those with special experience in the last world war.

The committee considered reports from the American Medical Association meeting at San Francisco, and particularly the increasing importance of certain economic and legal aspects of modern medicine. The committee recommends that the Council approve the inclusion in the program for the annual meeting in 1947 adequate discussion of some topic in medical economics.

The program for postgraduate instruction in various centers in the Commonwealth has been prepared and will be carried out with the co-operation of local committees through the fall and winter.

Dr. Root submitted a supplementary report, which was informational only and concerned itself with a suggested plan whereby a postgraduate clinical program to be held in the Boston hospitals might be combined with the annual meeting. He added that the details of the plan, which were still in the discussive stage, would be reported on later when and if they matured.

Also read into this record are the salient points of the new contract entered into by the Medical Service Administration of New Jersey with the Veterans Administration. These are as follows:

The new contract provides that Medical Service Administration will engage one or more competent medical representatives to be stationed at and operate from the Veterans Administration Regional Office.

The functions of this medical representative (or representatives) in brief shall be: (1) To certify a list of competent physicians throughout the State to render examinations and treatments to veterans. (2) To review the work of these physicians to the end that examinations and treatments are adequate, satisfactory and in accordance with established standards. (3) To make such investigations as Veterans Administration may request concerning complaints, deficiencies or inadequacies of reports made by examiners and to submit reports and recommendations thereon to Veterans Administration and Medical Service Administration. (4) To serve as liaison officer between Veterans Administration and Medical Service Administration but not as a supervisor of Veterans Administration activities or employees.

Veterans Administration will provide office space, equipment, clerical assistance and telephone service.

Veterans Administration will pay Medical Service Administration \$10,000 a year, payable quarterly in arrears, but the amounts so paid shall not exceed the amounts expended or incurred by Medical Service Administration.

The following comments made by New Jersey on this new plan were likewise read into the record:

Under the new plan authorizations for examinations and treatments will be issued directly from the Regional Office of Veterans Administration to the physician. The list of over 3000 participating physicians, in accordance with their type of practice, maintained under the previous plan will be continued. The fees paid physicians will remain the same as under the previous plan.

The new plan we believe will prove much more satisfactory than the first plan. It should expedite the medical care of the veteran and protect the interest of the private practitioner of medicine.

It must, however, be remembered that the administrative phase in providing medical care of service-connected disabilities among the 600,000 veterans of New Jersey by private physicians is a formidable problem. It is a new problem for both the profession and Veterans Administration, and that difficult administrative problems will arise and must continue to arise until a satisfactory solution for the entire problem is evolved. It is the sincere hope of Medical Service Administration that the problem will be satisfactorily met by the voluntary co-operation of the profession.

The committee in charge of this work looks upon the new contract which New Jersey has entered into as a modification of the Kansas Plan, which was fully explained at the meeting of the Council on April 10, 1946.

It now recommends that the Council approve the Kansas Plan so modified as to provide that the Blue Shield shall act as the liaison between the Veterans Administration and the physicians rendering this service in Massachusetts.

The Executive Committee recommends that the Council rescind its action of April 10, 1946, as previously outlined.

With regard to the second recommendation of the committee, the Executive Committee inquired whether or not the Blue Shield had been consulted in this matter. The chairman of the committee in charge of this work replied that it had and that it was in accord with the recommendation. The Secretary expressed the thought that, if the accord was in writing, it would clear the air and obviate the necessity of considerable debate before the Council.

In this connection the following letter was received:

MASSACHUSETTS MEDICAL SERVICE

September 18, 1946

Dwight O'Hara, M.D. President
Massachusetts Medical Society
8 Fenway
Boston, Massachusetts

Dear Doctor O'Hara:

In order that the Massachusetts Medical Society may be officially aware of the attitude of the Blue Shield Board of Directors relative to the Veterans Administration's proposed medical-care program, there are quoted below excerpts from minutes of meetings of the Blue Shield Board of Directors at which this matter was considered.

January 9, 1946—"Dr. Humphrey L. McCarthy presented to the Board a detailed explanation of the plans of the Veterans Administration for the care of veterans of World War II and discussed various plans under which the corporation might render assistance and participate in providing medical care for such veterans. It was the opinion of the directors that the corporation should co-operate with the Veterans Administration in every possible way provided that the financial stability of the corporation was not affected thereby."

April 10, 1946—"Voted that Dr. Hayden, the medical director, and Mr. Twomey, the attorney for the corporation be authorized to negotiate a contract with the Veterans Administration for the furnishing of medical and surgical service to disabled veterans and that Dr. Hayden, the Medical Director, be authorized to execute such contract on behalf of the corporation."

Respectfully,

[Signed] CHARLES G. HAYDEN
CHARLES G. HAYDEN, M.D.
Medical Director

The Executive Committee took no action on this recommendation pending the Council's action on the committee's first recommendation. The disposition of the Executive Committee, however, seemed favorable to this second recommendation provided the first recommendation was adopted by the Council and provided the Blue Shield was favorably disposed toward it.

Committee to Study the Revision of the Salaries of the Employees of the Society

The Executive Committee recommends that the Council adopt this report and the recommendations contained in it.

Committee on Finance

The Executive Committee notes that this report approves the recommendations called for in the previous report. It also approves of an additional appropriation of \$900 to cover the expenses of our representatives to the meeting of the House of Delegates of the American Medical Association to be held in Chicago in December, 1946. It was explained that this item was not covered in the annual budget because at that time there was no knowledge that such meeting of the House of Delegates of the American Medical Association was to be held.

The Executive Committee recommends that the Council adopt the recommendations contained in the report.

Committee on Postgraduate Assembly

In connection with this report the Executive Committee in a special manner directs the Council's attention to an implication which might be read in certain lines, namely, that monies taken in by the Society in a manner indicated in the report may be earmarked with regard to their expenditure. The Executive Committee points out that this may not be done. In support of this view, it quotes Chapter VI, Section 5, of the by-laws.

The Executive Committee recommends the acceptance of this report provided the provisions of Chapter VI, Section 5, are strictly adhered to.

Committee to Meet with the Massachusetts Hospital Association

This is an informational report. The Executive Committee recommends its acceptance.

Report of the Massachusetts Representatives to the House of Delegates of the American Medical Association

This report, which was prepared by Dr. D. Scannell, is informational. It is exceptionally well done. The Executive Committee recommends that the members of the Council read it carefully.

COMMUNICATIONS

The Executive Committee notes that the first two of these communications deal with the same subject. The John Hancock Mutual Life Insurance Company and the Liberty Mutual Insurance Company join in a request that the Massachusetts Medical Society set up a committee for the purpose of passing on the merits of individual sickness insurance plans as offered by old-line insurance companies.

These letters indicate that the inspiration, which directed them to be sent at this time to the President, rose out of the policy adopted by the House of Delegates of the American Medical Association at its San Francisco meeting. This policy had to do with a change of name whereby the Council on Medical Service and Public Relations is to be henceforth known as the Council on Medical Service and its function limited to a study of all types of insurance whose purpose is to meet the medical-care costs of sickness. This council will give its approval to any plan for this purpose which meets the standards which it will set and provided that the plan in question is first approved by a constituent state medical society.

The debate in the Executive Committee seemed to indicate that, although the Society through the Blue Shield is committed to insurance based on the medical-service principle as the best way to meet the medical-care costs of the low-income group, and, although it should continue to emphasize this principle, it should not assume opposition to other methods of insurance by means of which these costs might be met.

At this point in the proceedings, a discussion arose concerning the significance of the word "designate" as it appeared in the second suggestion. This discussion was participated in by Drs Fremont-Smith, Suffolk, and Baty, Middlesex South. The latter thought the word "define" should more properly be used. The former said that whatever language was adopted should make it clear that this step was taken for the purpose only of the Veterans Administration.

Dr Fremont-Smith moved as an amendment to the motion to adopt the recommendation of the Executive Committee that this recommendation be adopted subject to the insertion after the word "specialists," the words "for the purpose of the Veterans Administration only." This amendment was seconded by a councilor.

Dr Allan Butler, Suffolk, further amended the motion so as to provide that the word "define" be substituted for the word "designate." This amendment was likewise seconded by a councilor.

Dr Schadt asked if, after certain members were defined as specialists, those remaining were to be classified as general practitioners. The President answered in the affirmative.

The motion as amended by Dr Fremont-Smith and Dr Butler was adopted by vote of the Council.

The President said that the next matter before the Council was concerned with the third question submitted by the committee. He added that the committee suggested the following formula whereby the fees paid specialists might be distinguished from those paid the general practitioner:

The schedule of fees approved by the Council on April 10, 1946, shall be regarded as specialists' fees, and when the services called for in this schedule are rendered by the general practitioner, the compensation shall be 20 per cent less than that set forth in that schedule, with the understanding that if such a formula were adopted the committee be allowed a leeway not to exceed 5 per cent so that the fees finally set forth in the schedule shall appear in round numbers.

Dr Bagnall was recognized by the Chair. He spoke as follows:

So far as the fees are concerned, I should like to remind you that in April you adopted a fee schedule for Blue Shield to run this scheme, when it was finally adopted. I think it is fair to say that not many of you felt that the schedule of fees that was adopted was a schedule of fees that was reasonable. Due, perhaps in part at least, to the tremendous energy of the chairman of that committee, the schedule was adopted, and I had the pleasure of casting the only dissenting vote. But afterward I talked with a great many men, and I have not found but one since who thought that it was a fair fee schedule.

Now you come to the point of reducing that fee schedule by 20 per cent, which shows that the committee believes that the original fee schedule was not fair.

We could refer this schedule back to the committee, with the idea that they should make whatever adjustment the Veterans Bureau feels desirable, if it seems reasonable in the committee's point of view and if it feels that they are not letting the Society or the Council down.

It would be too big a job for the Council to go into the matter of fees again. The idea of dropping them 20 per cent for general practitioners seems fair enough. I have

not gone over the schedule on the basis of the 20 per cent reduction. I should prefer to leave it to the committee to iron out with the Veterans Administration on a basis that was mutually satisfactory.

Dr McCarthy moved the adoption of the suggestion offered by the committee. This motion was seconded by a councilor.

The President said that the Executive Committee approved the adoption of this suggestion. The motion was adopted by vote of the Council.

At that point, the Council went into executive session, from which it arose half an hour later.

The President said that the next matter before the Council was the recommendation of the committee that the Council rescind its action of April 10, 1946, whereby it was recommended that the Blue Shield be named the administrative agency in Massachusetts for the plan which concerned itself with the medical care by the civilian doctors of those for whom the Veterans Administration is responsible. The Council proceeded to discuss the matter informally.

Dr Fremont-Smith asked that a statement be made to the Council outlining the advantages and disadvantages of having the Veterans Administration set up its own administration in this state, and a further statement that would likewise outline the advantages and disadvantages of the Blue Shield's taking over the administration of this program. The President called Dr Smith's attention to the fact that the "Circular of Advance Information" told the story rather completely.

Dr Donald Munro, Suffolk, said that it was not entirely clear to him as to what the function of Blue Shield would be when and if it took over this administration. He asked if it would have any control of the fee schedule. He added that, as the result of what Dr Bagnall had said earlier in the meeting, there might be some question whether or not the Blue Shield, if they took over this administration, might want to reduce the fee schedule to the level of its own schedule. Dr Bagnall replied that he had no such thought in mind.

The President said that it was apparent that the committee made the recommendation because of the hopeless state that New Jersey got into in its attempt to administer a plan of this kind. He quoted Dr Bagnall as saying that in spite of New Jersey's difficulties the latter was of the belief that the Blue Shield could and would like to administer the plan in Massachusetts. He emphasized the fact that the Blue Shield had nothing to do with the fee schedule set up by the Council to cover medical services rendered under this program.

Dr Phippen said that it seemed clear to him that the Blue Shield was perfectly willing to go ahead with this proposition and because it was geared to handle the care of sick individuals on an insurance basis the Council would be well advised to let them handle this veterans' plan.

Dr Root moved the acceptance of the report. The motion was seconded, and it was so ordered by vote of the Council.

The President announced that this report contained two recommendations: first, that the Council direct the President to appoint a Committee on National Emergency Medical Service and to include in its membership sufficient representation of those with special experience in the last war, and secondly, that the Council approve of the inclusion in the program of the annual meeting in 1947 adequate discussion of some topic in medical economics. The President added that both these recommendations had been approved by the Executive Committee.

The first recommendation was adopted by vote of the Council on a motion by Dr Curley, seconded by Dr Phippen.

Dr Root moved the adoption of the second recommendation. This motion was seconded by Dr Curley, and it was so ordered by vote of the Council.

Dr Root moved the adoption of the report as a whole. This motion was seconded by Dr Phippen, and it was so ordered by vote of the Council.

Committee to Make a Survey of Malpractice Insurance in Massachusetts — Dr Carl Bearse, Norfolk, chairman.

This report (Appendix No. 4) was presented by the chairman. He said that it was purely informational and that, as the subject was still under investigation, no recommendations were being offered at that time.

He moved the acceptance of the report as one of progress. The motion was seconded by a councilor, and it was so ordered by vote of the Council.

Medical Advisory Committee to the Regional OPA — Dr Joseph Garland, Suffolk, chairman.

This report, which is as follows, was offered by the chairman:

The Medical Advisory Committee to the Regional OPA has met only once this year, on May 9, 1946. The main purpose of this meeting was to discuss the problems of various hospitals that had requested extra sugar. The question was referred to the Hospital Council of Boston for its advice, the result apparently being that this matter was left to the discretion of the committee.

Occasional applications for extra sugar rations for individuals have been referred to members of the committee, but otherwise its functions seem to be nearly over.

This report is offered for the information of the Council.

Dr Garland moved its acceptance. This motion was seconded by Dr Phippen, and it was so ordered by vote of the Council.

Report of the Committee to Meet with General Hawley with the View of Formulating a Program in Massachusetts for the Medical Care of Veterans and Their Dependents — Dr Humphrey L. McCarthy, Norfolk, chairman.

This report (Appendix No. 5) was presented by the chairman, who moved its acceptance. The mo-

tion was seconded by a councilor, and it was so ordered by vote of the Council.

The President called the attention of the Council to that part of the report which says that for the purposes of this program it is mandatory that the Council distinguish between the specialist and non-specialist. In this connection, he added, the Committee had posed three questions: (1) Shall such a differentiation be made? (2) If so, how shall it be arrived at? (3) What formula shall be used whereby the fees paid the specialist shall be differentiated from those paid to the general practitioner?

The President said that the Executive Committee recommended that the first question be answered in the affirmative.

A councilor moved that this differentiation be made. This motion was seconded.

Dr George L. Schadt, Hampden, asked the President if he would care to define the term "general practitioner." The President, while declining to answer this question, said that the Council might be able to arrive at the answer when it came to consider the suggestions which appeared later in this report.

Dr Hornor asked if legally the Council had any right to make such a differentiation. The President replied that any differentiation of the kind which the Council might make would have no standing under the law, that it was not intended that it should have, and that its sole purpose was to facilitate our program with the Veterans Administration.

Dr Carl Bearse said that he could not help but feel that the Council should hesitate before setting up such a differentiation. "Our method of practice," he continued, "has worked well in the past and it should work well in the future, even in so far as veterans are concerned."

On the invitation of the President, Dr McCarthy said that this differentiation was called for by the Veterans Administration and that it would have to be arrived at if the Society were to participate in the program. This motion was carried by vote of the Council.

The President said that the next question before the Council concerned itself with how this differentiation could be arrived at. In this connection, he added that the committee offered two suggestions: first, that a suitable questionnaire be submitted to each member of the Society asking him to designate in which one of the two groups he believes he should be placed, second, to designate as specialists all those so certified by the specialty boards and those physicians who state that they limit their practice to a special field or who practice a specialty in an approved hospital as a member of that hospital's regular staff. The President said that the Executive Committee recommends that the Council approve the second suggestion.

Dr Richard M. Smith, Suffolk, moved the adoption of the recommendation of the Executive Committee. The motion was seconded by a councilor.

Committee Appointed to Confer with the Massachusetts Hospital Association — Dr Walter G Phippen, Essex South, chairman

The report, which was offered by the chairman, is as follows

The material pertaining to the Gallupe Plan for furthering the usefulness of graduates of substandard schools in hospitals was sent to every hospital in the Commonwealth, together with the remarks made on this subject at the annual meeting of the Society. Otherwise there has been no activity of this committee.

The President said that this was a report of progress. It was moved that it be accepted as such. This motion was seconded, and it was so ordered by vote of the Council.

Report of the Massachusetts Representatives to the House of Delegates of the American Medical Association — Dr David D Scannell, Norfolk

This report (Appendix No 7) was submitted by the President in Dr Scannell's absence, who commented on the thorough manner in which the report had been prepared.

The Secretary said that Dr Scannell had been appointed by the speaker of the House of Delegates of the American Medical Association to a committee which had already met to study the report of Rich and Associates, with a view of presenting an analysis of it to the House of Delegates when it meets in December. He explained that at the direction of the Board of Trustees, this firm had been employed to conduct a survey as to how the public relations of the American Medical Association might be improved.

Dr Scannell's report was accepted by vote of the Council.

COMMUNICATIONS

The following letters to the President, each dealing with the same subject, were presented

JORN HANCOCK MUTUAL LIFE INSURANCE COMPANY
Home Office Boston Massachusetts
August 7 1946

Dr Dwight O'Hara, President
Massachusetts Medical Society
8 Fenway Boston Massachusetts

Dear Dr O'Hara,
Our company has for three quarters of a century had a sincere interest in the health and welfare of the people of this country. By providing, through insurance, a medium for sharing certain risks to which all men are liable but which fall unevenly on a few, we believe that we have contributed to general social stability and the improvement of our way of life.

At the recent convention in San Francisco we believe that the American Medical Association confirmed the opinion already held by a large proportion of the profession that in order to accomplish the desired protection of the public in the most rapid and efficient manner the doctors should co-operate with all reputable types of health insurance. Two approaches were outlined for determining the standards of such insurance, in so far as they relate to the practice of medicine: one a joint advisory body to be set up by the American Medical Association to study the problems inherent in this risk and the other an implied recommendation to the state societies to set up the machinery for passing on the merits of individual plans and the reciprocal responsibilities of the doctor and the insurance carrier which they involve. Our company desires to co-operate with the doctors in both these procedures.

It is our opinion that the pre-eminent position of the Massachusetts Medical Society in the councils of the profession makes it the logical leader in this field. It would give our company great satisfaction if your society would join with us in undertaking this public duty. While we cannot speak officially for any of the other insurance companies

we have reason to believe that such a move by your society would be welcomed by them and that they too would be happy to participate in the work.

We believe that the public would appreciate this constructive action.
Very truly yours
(Signed) H MAYNARD REES M D
H MAYNARD REES M D, Director
Medical Service Insurance

LIBERTY MUTUAL INSURANCE COMPANY
175 Berkeley Street Boston Massachusetts
August 7 1946

Dr Dwight O'Hara, President
Massachusetts Medical Society
8 Fenway Boston Massachusetts
Dear Dr O'Hara

We have followed closely the hearings before the Senate Committee on Education and Labor on the National Health Act of 1945. We have also been much interested in the recent proceedings of the House of Delegates of the American Medical Association at San Francisco.

We gather that the American Medical Association has not weakened in its opposition to compulsory health insurance but recognizes meanwhile that something more must be done than to oppose legislation regarded as undesirable. We understand the Association is thoroughly alive to the necessity for pushing voluntary plans for prepayment insurance to cover surgical and hospital expenses and convinced that a large enrollment in voluntary plans is essential. Will not give exclusive support to any one type of plan but will approve any plan which meets its requirements.

This action by the House of Delegates is constructive but should be implemented by action by the state societies since the national organization will act only on plans already approved at the local level. The Massachusetts Medical Society has attained a pre-eminent position among groups of doctors and has a record for achievements in the public interest. Therefore it would be most significant if your organization would take a position of leadership in this field comparable to what it has accomplished in other areas.

The problem demanding solution is how to provide enough people with prepaid surgical hospital and medical-care insurance at a sufficiently moderate price to meet the demand of the public for coverage without the necessity for Government operation in this field. It will not meet the problem merely to point out that certain plans are available; it will be necessary to take definite constructive action to design solutions that meet the needs of the people in terms of the coverage furnished and the number of people protected.

In our opinion the need of the public can be met, within the frame of the competitive enterprise system by co-operation between the doctors, employers and existing insurance facilities. The employer should be included in the formula because it is essential to have administrative supervision, improved industrial hygiene, practical provision for the practice of preventive medicine and groups large enough to reduce handling costs to a minimum. The employer-employee relationship is the keystone of the arch of production which must be increased if the economy is to enjoy improved standards of medicine, improved standards of health and improved standards of living.

Further, we believe that there should be a number of different plans available through a number of different facilities. We believe that competition among the several plans that may become available will achieve the best final results for the greatest number of people.

We are convinced that unless this problem can be met at a "public service" level by both the insurance companies and the doctors seeking a solution without regard to their selfish interests, socialized medicine will be the inevitable outcome.

Motivated by these thoughts we respectfully make the suggestion to the Massachusetts Medical Society that it consider favorably the proposition that it work to develop a plan of action under which the resources, facilities and experience of the insurance companies would be enlisted in a co-operative effort to achieve a practical solution to the need of the people for an extension of nonoccupational accident and health insurance within the framework of our existing economic society.

Very truly yours
(Signed) S BRUCE BLACK
S BRUCE BLACK, President

The President said that the Executive Committee had reviewed these communications and recommended that they be referred to the Committee on Public Relations with the suggestion that a subcommittee be set up by that committee for the purpose of the study outlined in them.

It was moved that the recommendation of the Executive Committee be adopted. This motion was seconded, and it was so ordered by vote of the Council.

Two communications received by the Secretary were presented to the Council. One (Appendix No 8) was from Dr George F Lull, secretary of the American Medical Association, and the other (Appendix No 9) was from Dr Frank H Lahey, chairman of the Directing Board, Procurement and Assignment Service.

Dr McCarthy said that at the meeting of the Executive Committee he was instructed to ascertain in writing the views of the Blue Shield in this matter, as mentioned in the report of the Executive Committee. He added that he had complied with this directive and that the letter which appeared in the report of the Executive Committee was the answer received. When he had heard of the difficulty in New Jersey, he continued, both he and Dr Tighe wrote to New Jersey and at the same time informed the Blue Shield of the difficulties in that area. He said that this recommendation in the report was inspired out of a sense of caution.

Dr Bagnall said that during the last three days of the current week the Blue Shield people all over the country planned to hold a meeting for the discussion of this subject and that undoubtedly much information on it would become available.

Dr Munro said that the Council seemed to be getting nowhere rapidly. He moved that this subject be laid on the table to be withdrawn when more information with regard to it is available. This motion was seconded, and it was so ordered by vote of the Council.

The order of the day was moved. The motion was seconded and it was so ordered by vote of the Council.

Committee Appointed to Study Revision of the Salaries of the Employees of the Society — Dr Charles J Kickham, Norfolk, chairman

In the absence of the Chairman, this report (Appendix No. 6) was presented by the President, who said that it called for an extra appropriation of \$1,332 for the purposes outlined in the report. He added that this appropriation had been approved by the Executive Committee.

Dr Lester M. Felton, Worcester, moved that the report be accepted and the recommendations contained in it adopted. The motion was seconded by a councilor. It was so ordered by vote of the Council.

Committee on Finance — Dr Robert W. Buck, Middlesex South, chairman

This report, which is as follows, was presented by the chairman.

The Committee on Finance has unanimously approved the salary increases as recommended by the special committee appointed to study this subject, such increases requiring an extraordinary appropriation in the amount of \$1,332 for the period from July 1, 1946, to December 31, 1946.

The following correspondence was submitted by the committee as a supplementary report.

August 24, 1946

Dr Robert W. Buck, Chairman
Committee on Finance
5 Bay State Road
Boston 15, Massachusetts
Dear Dr. Buck:

Dr. Tighe has called my attention to the fact that there is to be a meeting of the House of Delegates in Chicago in December of this year.

This is, of course, an item which was not anticipated at the time the budget for 1946 was passed upon. It would therefore, seem to me wise for the Committee on Finance to recommend to the Council that an extraordinary appropriation of \$500 be made to cover the expenses of the Massachusetts delegates to this meeting.

If you and your committee approve of making this request, I think a line from you to that effect would be all that is necessary. If possible, this should be in the Secretary's hands on or before next Wednesday, August 28, so that it may be mimeographed and added to the business for the October meeting.

Thanking you for consideration of this matter, I am

Sincerely yours,

[Signed] DWIGHT O'HARA
DWIGHT O'HARA, M.D., President

August 26, 1946

Dr. Michael A. Tighe, Secretary
The Massachusetts Medical Society
8 Fenway
Boston 15, Massachusetts
Dear Dr. Tighe:

Dr. O'Hara has asked that the Committee on Finance recommend to the Council that an extraordinary appropriation of \$500 be made to cover the expenses of the Massachusetts delegates to the December meeting of the House of Delegates in Chicago.

On behalf of the Committee on Finance I recommend this appropriation, although owing to the shortness of time not all of the members of the committee have yet been able to express their approval. When this approval is obtained, it will be forwarded to you.

Very truly yours,

[Signed] ROBERT W. BUCK
ROBERT W. BUCK, M.D.
Chairman, Committee on Finance

September 4, 1946

Dr. Michael A. Tighe, Secretary
The Massachusetts Medical Society
8 Fenway
Boston 15, Massachusetts
Dear Dr. Tighe:

I have received the unanimous approval of the Committee on Finance of the extraordinary appropriation of \$500 to cover the expenses of the Massachusetts delegates to the December meeting of the House of Delegates in Chicago.

Sincerely yours,

[Signed] ROBERT W. BUCK
Chairman, Committee on Finance

Dr. McCarthy moved the adoption of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee on Postgraduate Assembly — Dr. Leroy E. Parkins, Suffolk, chairman

The report, which was offered by the chairman, is as follows:

The committee has joined with representatives of the other New England state medical societies to form an executive committee, which has appointed a program and other committees necessary to carry out the work of arranging the assembly. The program will be published in the *New England Journal of Medicine*, issue of September 12, 1946. All the speakers are distinguished members of the profession.

The symposium to be presented on the medical care of veterans in the Anglo-Saxon countries is of timely interest and importance.

On vote of the Executive Committee it was decided to hold the assembly in a hotel, also it was voted to have technical exhibits to help pay expenses for this assembly and provide funds to organize a better program for next year.

Dr. Parkins moved the adoption of the report provided that the following language appearing at the end of the report be deleted: "and provide funds to organize a better program for next year." He said that this deletion would bring the report into conformity with the views of the Executive Committee, the latter having recommended that the report be adopted, provided Chapter VI, Section 5, of the by-laws be strictly adhered to. Dr. Parkins's motion was seconded by a councilor, and it was so ordered by vote of the Council.

APPENDIX NO. 2

REPORT OF THE COMMITTEE ON LEGISLATION

In the field of federal legislation a statement of the attitude of the Massachusetts Medical Society on Senate 1606 was sent by the special Subcommittee on Federal Legislation (Drs. Reginald Fitz, E S Bagnall, Dwight O'Hara, M A Tighe and J C McCann), to the United States Senate Committee holding hearings on this bill. This statement outlined the basic principles of adequate medical care as adopted by our society. It pointed out the shortcomings of Senate 1606, and gave reasons for disapproving the bill. This subcommittee continues to function in all matters pertaining to federal legislation.

In the field of state legislation, the end of the 1945-1946 session of the General Court brought a successful conclusion to our efforts. A total of eighty-four bills were considered, of which thirteen were approved and sixteen opposed. A brief statement of the disposal of some of the more important bills may be of interest.

The three antivivisection bills (H 117, H 1339 and H 1340) were defeated. Opposition to these bills was ably banded by a special committee consisting of Dr. John Conlin (chairman), of Tufts Medical School, Dr. Charles Lund, of Harvard Medical School, Dr. George Maisson, of Boston University School of Medicine, and Rev. Father McGowan, of the Associated Catholic Hospitals.

A bill (S 46, later H 1875), to establish a special board for licensing chiropractors, was defeated in the House. An adverse committee report was given on a similar bill (H 601) to establish a board of osteopathy.

A bill (S 45) to open hospitals to all licensed physicians was defeated in the Senate.

The four bills (S 118, S 263, H 299 and H 301) to give graduates of Middlesex Medical School since January 1, 1944, the right to take examinations for license to practice in Massachusetts were replaced by a bill that restricted this privilege to men who, when medical students, were citizens of Massachusetts. This bill, which applies to some twenty-eight men, has become a law. Since Massa-

The President said that these letters were informational and required no action by the Council

APPOINTMENTS

The President then announced the following *ad interim* appointments

To the Council

- Dr Fred A Bartlett, Norfolk South, to take the place of Dr Charles S Adams, deceased
- Dr Joseph H Carey, Norfolk, to take the place of Dr Henry M Landesman, deceased
- Dr Franklyn P Bousquet, Worcester, to take the place of Dr John J Dumphy, resigned
- Dr Eugene L Richmond, Worcester, to take the place of Dr Gordon Berry, resigned

To the Board of Censors

- Dr Fred A Bartlett, Norfolk South, as supervisor, to take the place of Dr Charles S Adams, deceased
- Dr Paul P Henson, Barnstable, as supervisor

To the Executive Committee of the Council

- Dr Franklyn P Bousquet, Worcester, as alternate, to take the place of Dr John J Dumphy, resigned

To the Committee on Membership

- Dr Samuel N Vose, Suffolk, as chairman *pro tempore*, to take the place of Dr Harlan F Newton, resigned
- Dr Peirce H Leavitt, Plymouth, as chairman, to take the place of Dr Vose
- Dr Lewis S Pilcher, Middlesex South

To the Committee on Nominations

- Dr Franklyn P Bousquet, Worcester, as alternate, to take the place of Dr John J Dumphy, resigned

To the Committee to Confer with the Massachusetts Farm Bureau Federation

- Dr Elmer E Thomas, Hampshire, to take the place of Dr Joseph D Collins, resigned

To the Committee to Confer with the Massachusetts Hospital Association

- Dr Nicholas S Scarcello, Worcester, to take the place of Dr John Fallon, resigned

To the Committee on Postpayment Medical Care

- Dr Elmer E Thomas, Hampshire, to take the place of Dr Joseph D Collins, resigned

To the Committee on Tax-Supported Medical Care

- Dr Thomas Hunter, Worcester, as chairman, to take the place of Dr John J Dumphy, resigned

To the Committee to Meet with General Hawley

- Dr James K Bragger, Norfolk, to take the place of Dr John J Dumphy, resigned

To the Committee to Study Revision of Salaries of Employees of the Society

- Dr Charles J Kickham, Norfolk, chairman
- Dr Robert W Buck, Middlesex South
- Dr Robert N Nye, Suffolk

To the Committee to Study the Income Level of Blue Shield

- Dr Charles F Wilnsky, Suffolk, chairman
- Dr Norman H Bruce, Middlesex South
- Dr Raoul L Drapeau, Middlesex North
- Dr Henry L Kirkendall, Worcester
- Dr John W Spellman, Norfolk

To the Committee to Study Increase in Assessment of Dues

- Dr Frank R Ober, Suffolk, chairman
- Dr N Newall Copeland, Berkshire

- Dr Edwin D Gardner, Bristol South
- Dr Kenneth L MacLachlan, Middlesex East
- Dr John W McKoan, Worcester

To the Subcommittee on National Legislation

- Dr Elmer S Bagnall, Essex North, chairman
- Dr Reginald Fitz, Suffolk
- Dr James C McCann, Worcester
- Dr Michael A Tighe, Middlesex North

To the Subcommittee on Veterans Affairs

- Dr Charles Bradford, Suffolk
- Dr Stephen Brown, Hampshire
- Dr William M Carr, Plymouth
- Dr Leo R Desmond, Norfolk
- Dr Spencer C Flo, Franklin
- Dr Merrill F Gardner, Bristol South
- Dr Willis N Gowen, Middlesex East
- Dr Leonard W Hill, Bristol North
- Dr Sheldon L Hunt, Barnstable
- Dr Thomas Hunter, Worcester
- Dr John C McGirr, Middlesex South
- Dr Frank P Morse, Jr, Essex South
- Dr F K Paddock, Berkshire
- Dr Ensio K F Ronka, Norfolk South
- Dr Louis B Simard, Essex North
- Dr Thomas J G Tighe, Middlesex North

To the Council of the New England State Medical Societies

- Dr Norman A Welch, Norfolk, to take the place of Dr Dwight O'Hara, resigned

In reference to the Committee on Veterans Affairs, Dr Curley asked who represented Worcester North. The President said he would look this matter up after the meeting and let Dr Curley know. Dr Curley said he asked the question because as the list was read there was no one accredited to that district. The President said he would correct that situation within twenty-four hours.

The President's appointments were confirmed by vote of the Council.

NEW BUSINESS

Dr Bagnall moved that the committee appointed to meet with General Hawley with a view of formulating a program in Massachusetts for the medical care of veterans and their dependents be reorganized so as to consist of five members among whom would be adequate representation of the Blue Shield. This motion was seconded.

There was some discussion whether or not the motion should be referred, under the Council rules, to the Committee on Public Relations. Dr Hornor expressed the thought that it should be so referred on the basis that the committee in question was a subcommittee of the Committee on Public Relations. Dr McCarthy said that this committee was a special committee.

The President ruled that the motion would not be put to the Council, and in so ruling he said that it was within his province to act on the subject matter of the motion without a formal vote by the Council. The Council acquiesced in the ruling. There being no further business before the Council, the President announced it adjourned at 12 50 p m.

APPENDIX NO 2

REPORT OF THE COMMITTEE ON LEGISLATION

In the field of federal legislation a statement of the attitude of the Massachusetts Medical Society on Senate 1606 was sent by the special Subcommittee on Federal Legislation (Drs Reginald Fitz, E S Bagnall, Dwight O'Hara, M A Tighe and J C McCann), to the United States Senate Committee holding hearings on this bill. This statement outlined the basic principles of adequate medical care as adopted by our society. It pointed out the shortcomings of Senate 1606, and gave reasons for disapproving the bill. This subcommittee continues to function in all matters pertaining to federal legislation.

In the field of state legislation, the end of the 1945-1946 session of the General Court brought a successful conclusion to our efforts. A total of eighty-four bills were considered, of which thirteen were approved and sixteen opposed. A brief statement of the disposal of some of the more important bills may be of interest.

The three antivivisection bills (H 117, H 1339 and H 1340) were defeated. Opposition to these bills was ably handled by a special committee consisting of Dr John Conlin (chairman), of Tufts Medical School, Dr Charles Lund, of Harvard Medical School, Dr George Maisson, of Boston University School of Medicine, and Rev. Father McGowan, of the Associated Catholic Hospitals.

A bill (S 46, later H 1875), to establish a special board for licensing chiropractors, was defeated in the House. An adverse committee report was given on a similar bill (H 601) to establish a board of osteopathy.

A bill (S 45) to open hospitals to all licensed physicians was defeated in the Senate.

The four bills (S 118, S 263, H 299 and H 301) to give graduates of Middlesex Medical School since January 1, 1944, the right to take examinations for license to practice in Massachusetts were replaced by a bill that restricted this privilege to men who, when medical students, were citizens of Massachusetts. This bill, which applies to some twenty-eight men, has become a law. Since Massa-

chusetts students are now provided for, all future legislation directed against the Approved Act may be successfully opposed.

A bill (H 1822), which exempted veterans from legislation enacted since September 16, 1940, in respect to boards of registration and which adversely affected the Approval Act, was reported out of a conference committee of the Senate and House, with the section applying to the professions deleted. With this deletion the bill was passed by the Legislature to become Chapter 577 of the Acts of 1946.

Of the four bills (S 404, S 405, and S 406 and S 407) to revoke the charters of nonfunctioning or substandard medical schools, only S 407, which revoked the charter of the College of Physicians and Surgeons as of 1949, was passed.

A bill (H 230), initiated by Dr. Gallupe, of the Massachusetts Board of Registration in Medicine, was passed. This bill enables Massachusetts to have license reciprocity with other states.

The attitude of the members of the General Court toward the Massachusetts Medical Society is becoming increasingly co-operative. Most legislators now realize that our efforts are directed toward maintaining high standards of medical practice as an important means of safeguarding the public health. Much of this goodwill may be attributed to the well directed educational efforts of our legislative counsel, Mr. Charles Dunn.

DAVID L. BELDING, *Chairman*

APPENDIX NO 3

REPORT OF THE COMMITTEE ON PUBLIC RELATIONS

The Committee on Public Relations recommended that the President appoint a representative of the Massachusetts Medical Society to help the Academy of Pediatrics survey of facilities and need for facilities in the care of children. This question had been referred to the Committee on Public Relations by the Council of the Massachusetts Medical Society at its meeting on May 21, 1946. After the adoption of the motion President O'Hara announced that he would appoint Dr. David Sherwood as representative of the Massachusetts Medical Society to help the proposed survey of the Academy of Pediatrics.

The Committee on Public Relations accepted, with thanks, Dr. Ellison's report as chairman of the Subcommittee to Consult with the Advisory Committee of the Industrial Accident Board and this report has since been circularized to the members of the Massachusetts Medical Society.

The question of having a Woman's Auxiliary to the Massachusetts Medical Society was referred back for further investigation to the subcommittee appointed to study this question.

The Committee on Public Relations discussed the letter submitted by Dr. Shields Warren, of the New England Deaconess Hospital, in protest against the paying by insurance companies of ward rates, since these rates are set at less than the cost of caring for the patient. After much discussion the committee decided that this is a problem for the Massachusetts Hospital Association and asked to be relieved of further duties in connection with this letter.

ALBERT A. HORNOR, *Secretary*

APPENDIX NO 4

REPORT OF THE COMMITTEE TO MAKE A SURVEY OF MALPRACTICE INSURANCE IN MASSACHUSETTS

Two meetings were held, the second was attended by the chairman of the Committee on Medical Defense. Discussions were held with representatives of several insurance companies, and considerable data were obtained from the Insurance Department at the State House.

Group malpractice insurance as such cannot be written in Massachusetts. An opinion rendered by the Attorney General in 1923 stated, "A group or blanket policy of liability insurance may not be issued to an association of dentists or physicians."

There are at least ninety-four insurance companies authorized to write malpractice insurance in this state, but no information is available at present to indicate which companies

engage in this type of underwriting. About nine companies are probably doing most of this business. The Medical Protective Company, the U. S. Fidelity and Guaranty Company, and the Lumbermen's Mutual Casualty Company probably underwrite the largest number.

We understand that a considerable number of physicians in the Massachusetts Medical Society carry no insurance at all, some are apparently content to be defended by the Society and pay the cost of settlements, or judgments awarded by the court or jury, themselves. Others, chiefly graduates of unapproved medical schools, cannot obtain such insurance.

The premiums charged by those companies from whom we have been able to get figures are not uniform. It was stated that their premium rate is based on their experience in the Commonwealth. For example, for the same type of insurance for which the Medical Protective Company charges \$19 in Massachusetts, this same company charges \$16 in Pennsylvania. A company starting to underwrite malpractice insurance in a new territory may feel they can begin with a lower rate than charged by companies doing business for some time. But whether they can maintain such a rate will depend on their subsequent experience.

The Hartford Accident and Indemnity Company suggested the establishment of a committee within the Society to advise both the doctor, against whom a claim has been made, and the representative of the insurance company. This committee would study all claims or possible claims and advise both physician and insurance company as to the method to be pursued. According to their representative, New Hampshire has such a committee and has been able in seven years to reduce the cost of insurance for a surgeon with \$5,000/15,000 limits from \$60 to \$30 a year. The Medical Defense Committee of our society is consulted only by physicians carrying no malpractice insurance. Incidentally, should a plan similar to the New Hampshire one be adopted, the Hartford Accident and Indemnity Company will be glad to write policies subject to limits of \$10,000/30,000 at annual premiums of \$25 for general practitioners (exclusive of major surgery), \$32 for surgeons, and \$74 for x-ray specialists. This company will not differentiate as regards school but every applicant is checked by a credit bureau.

The American Policyholders' Insurance Company submitted a plan.

All members of good standing in the Society would be eligible.

No minimum or maximum number of members would be required.

The rates at the beginning would be as follows:

LIMIT	GROSS RATE	NET RATE (15% dividend)
\$10,000/30,000	\$20	\$17.00
15,000/45,000	22	18.70
20,000/60,000	24	20.40
25,000/75,000	26	22.10
50,000/150,000	28	23.80
100,000/300,000	30	25.50

These rates would be applied to all physicians and surgeons except those giving x-ray therapy, in which case the rates would increase 50 per cent. The above quoted rates are subject to a dividend of 15 per cent, which the company has paid to policyholders with this type of insurance uninterruptedly since its inception.

The procedure which they would employ is to be based on an agreement with the Society covering all features of the plan and individual policies are to be issued to each subscribing member. They will group the experience from time to time of the individual members as one unit and use the experience as the basis for rate adjustments. No physician other than a member of the Society would be eligible for insurance in this unit. After a period of twenty to twenty-two months, they expect to be able to judge their experience and will make revisions accordingly. The representative of the company feels that under this method of operation the members of the Society "could look forward with optimism to reduced rates from time to time while this plan is in operation." The company states they have been insuring physicians, dentists, and hospitals for many years and that they have written many county societies and specialist societies as groups. They are presently negotiating with some twenty-four medical societies.

The Lumbermen's Mutual Casualty Company, which has been writing malpractice insurance for over eight years in Massachusetts, submitted the following proposition

\$5,000/15,000 coverage to the general practitioner for \$25 the first year

A 20 per cent dividend would bring the second-year cost down to \$20

If one third of the membership of the Society is secured, they will give an additional \$5 discount, which will make the net cost \$15 per year

This applies to general practitioners only No figures were furnished as to surgeons and radiologists

The Medical Protective Company has reduced its limits to \$5,000/15,000 They state that the larger limits carried by physicians made the malpractice situation worse They feel that it increases the activity of the damage-suit lawyers and that this interest will lessen with smaller insurance targets, that it centers the attention of courts and juries on the question of insurance rather than on the issues in the trial, that it creates fictitious estates far beyond the actual means of the professional men carrying them, that it serves to invite large verdicts when there was no occasion for them, that it handicaps, or makes impossible, any reasonable compromises in difficult situations where such compromises are desired by the assured, that it increases rather than decreases the actual protection of a doctor and creates insurance for the damage-seeking plaintiff To follow this line of thought still further, it may be argued that any indemnity insurance may encourage the bringing of actions The plaintiff and his attorney may feel that any suit, if an insurance company is back of a physician, has a nuisance value. Relatively few suits against physicians when defended by a state medical society have been won in court

The Medical Protective rates are as follows

TYPE OF PRACTICE	LIMIT	RATE
Restricted surgery	\$2,500/ 7,500	\$19
Restricted surgery	\$5,000/15,000	22
Unrestricted surgery	2,500/ 7,500	25
Unrestricted surgery	5,000/15,000	30

Companies writing malpractice insurance in Massachusetts have to file an annual report at the State House Since all companies except the Medical Protective handle various types of insurance and "lump" their figures, only the Medical Protective figures are presented, as follows

RATE	INCOME	DISB	NET PREMIUMS WRITTEN	NET LOSSES	TOTAL ASSETS	SURPLUS TO POLICY HOLDERS	PER- CENT- AGE LOSSES IN SUITS TO PREMIUMS EARNED
1945	\$794,494	\$702,603	\$717,747 *46,850	\$133,178 *11,405	\$2,767,886	\$832,333	30.30
1944	726,369	674,047	647,809 *41,641	157,356 *13,117	2,675,482	787,607	15.84
1943	(Figures not available as statement is in hands of binder)						
1942	814,449	739,353	737,267 *48,701	242,123 *10,720	2,596,210	689,663	29.58
1941	921,095	1,283,343	829,343 *57,407	344,546 *15,750	2,520,434	663,725	31.69
1940	987,730	1,114,908	894,525 *62,785	417,167 *24,317	2,883,700	928,569	35.67

*These figures indicate Massachusetts business

The United States Fidelity and Guaranty Company begins coverage from \$10,000/30,000 Their rates vary according to specialty, ranging from \$19 to \$70, and they state that 40 per cent of their clients in Massachusetts qualify for the basic rate of \$19 This company has agreed to a 5 per cent decrease for all specialists, except x-ray This company is carrying hundreds of policies written in excess of \$10,000/30,000 A great many carry \$50,000/150,000 and some are \$100,000/800,000 This company entertains applications from graduates of unapproved schools who hold membership in the Society

In evaluating the relative merits of companies writing malpractice insurance, factors other than their financial stability and rates must be considered The experience and ability of their legal counsel are important, since malpractice suits are a highly specialized type of legal work Experienced agents may possibly also be of value It must not be overlooked,

however, that these agents usually work on a commission and that this commission is added to the cost of the premium

In view of the record of successful defense of suits by state medical societies, the advisability of the Massachusetts Medical Society undertaking its own indemnity insurance deserves consideration This idea is not new, it was mentioned by Dr Arthur W Allen in his report of the Committee on Medical Defense to the Council on February 6, 1946, and by Dr Walter P Bowers at a Council meeting twenty-five years ago

This report is submitted as one of progress Much more fact finding and study is necessary before recommendations can be made

CARL BEARSE, Chairman

* * *

The committee submitted a supplementary report giving data on the Mutual Protective Company for the years 1930-1940 (Table 1)

TABLE 1 Data on the Medical Protective Company (1930-1940)

YEAR	TOTAL INCOME	TOTAL DISBURSE- MENTS	MAS- SACHU- SETTS PREMI- UMS WRIT- TEN	MAS- SACHU- SETTS LOSSES PAID	TOTAL ADMITTED ASSETS	SURPLUS	PER- CENT- AGE OF LOSSES IN- CURRED TO PRE- MIUMS EARNED

APPENDIX NO 5

PROGRESS REPORT OF THE COMMITTEE TO MEET WITH GENERAL HAWLEY WITH VIEW OF FORMULATING PROGRAM IN MASSACHUSETTS FOR MEDICAL CARE OF VETERANS AND THEIR DEPENDENTS

The fee schedule approved by the Council of the Massachusetts Medical Society on April 10, 1946, was forwarded to the Veterans Administration in Washington

Word has been received from the Administration which alters only the form that this schedule should take No criticism of the fees submitted was offered

This communication indicated that a fee schedule should be submitted on two forms one to cover outpatient service and the other to cover service to veterans while confined to their homes or to hospitals The form covering the former service accompanied this communication It is herein reproduced

Fee Schedule for Outpatient Service

Submitted to Veterans Administration By

CLINICAL LABORATORY TESTS

- (1) Total and differential blood count including colorimetric hemoglobin estimation
- (2) Blood smear for malaria
- (3) Urinalysis, routine chemical and microscopic
- (4) Blood Wassermann (complement-fixation)
- (5) Blood Kahn (precipitation)
- (6) Spinal-fluid Wassermann (complement-fixation)
- (7) Spinal-fluid Kahn (precipitation)
- (8) Chemical examination of blood complete, including creatinine urea dextrose, nitrogen (or NPN) and uric acid
- (9) Sputum examination for tuberculosis (plain smear)
- (10) Determination of basal metabolic rate

SERVICES BY NONSPECIALISTS

- (11) Examination to determine need of hospitalization
- (12) Complete general routine physical examination
- (13) Office visit with treatment
- (14) Day visit to home or hospital (within city limits)
- (15) Night visit to home or hospital (9-00 p.m.-7-00 a.m.) (within city limits)
- (16) Charge for mileage one way for day or night visit outside city limits in addition to appropriate fee

EXAMINATIONS BY SPECIALISTS

- (17) General surgical
- (18) Orthopedic
- (19) Physical examination of heart
- (20) Complete examination of heart, including electrocardiogram
- (21) Electrocardiogram with interpretation
- (22) Physical examination of lungs
- (23) X-ray of lungs, flat plate
- (24) X-ray of lungs, stereoscopic
- (25) Gastrointestinal, including barium meal, x-ray and fluoroscopy
- (26) Dermatological
- (27) Allergy investigation (protein sensitization tests) including complete examination and report
For each 25 tests
- (28) Genitourinary examination without cystoscopy
- (29) Gynecological
- (30) Proctological
- (31) Psychiatric examination, complete
- (32) Neurological examination, complete
- (33) Examination of ears, nose and throat
- (34) Special ear examination, including audiometric test with chart
- (35) Special ear examination, including caloric or Barany test with report
- (36) Examination of eyes (to include either a copy of the prescription ordered or the retinoscopic correction of the refractive error, the fundus and field findings—the latter by chart in all cases of optic atrophy)
- (37) Examination of eyes with refraction if mydriatic is used (to include either a copy of the prescription ordered or the retinoscopic correction of the refractive error the fundus and field findings—the latter by chart in all cases of optic atrophy)
- (38) Examination by internist to determine diagnosis

TREATMENT BY SPECIALISTS

- (39) Dermatological first visit
- (40) Dermatological each subsequent visit
- (41) Ear, nose and throat first visit
- (42) Ear, nose and throat each subsequent visit
- (43) Ophthalmological first visit
- (44) Ophthalmological each subsequent visit
- (45) Psychiatric treatment (psycho-therapeutic conference), session of at least 50 minutes
- (46) Psychiatric treatment (psycho-therapeutic conference), session of 25 minutes or less
- (47) Neurological treatment (treatment is understood to be the usual follow-up care and observation after diagnosis has been made at original neurological examination)
- (48) Intravenous sodium amylal procedure

STANDARDS FOR NEUROPSYCHIATRISTS TO BE DESIGNATED FOR THERAPY PSYCHIATRISTS

Qualifications

- a Certified in psychiatry by American Board of Psychiatry and Neurology, or
- b Possession of one of following ranks in an accredited medical school
 - 1 Any professional rank in psychiatry
 - 2 Associate in psychiatry
- c Experience
 - 1 At least four years of two half days a week in an accredited mental hygiene clinic or similar institution in which modern therapeutic principles and techniques were practiced, or
 - 2 Certification by the American Psychoanalytical Association and four years practice of psychiatry using this, or other forms of modern psychiatric treatment or
 - 3 Two years' certified training and experience in the armed forces or in any other accredited institution in which intensive individual therapy was practiced and taught, with two additional years of similar practice, either private or institutional

NEUROLOGISTS

Qualifications

- a Certification in Neurology by American Board of Psychiatry and Neurology

We were informed by the Veterans Administration that the form which had to do with service rendered to veterans while confined to their homes and hospitals would be received later

The committee calls attention to the fact that the completion of the form submitted and herein reproduced makes it mandatory that the Society distinguish between the specialist and the nonspecialist, except in regard to psychiatrists and neurologists, in which instances the Veterans Administration itself sets the qualifications

The committee is very much aware of the difficulties which attend such a differentiation. It is its opinion that such differentiation is not within the scope of its authorization. It therefore finds it necessary to submit three questions to the Council. Shall such a differentiation be made? How shall it be arrived at? What formula shall be used whereby the fees paid to the specialist shall be differentiated from those paid to the general practitioner?

The committee has given much thought to this difficult subject. For the purposes of facilitating the discussion attending it, it submits two ideas with regard to the second question, provided the first question is answered in the affirmative. These are as follows

A suitable questionnaire be submitted to each member of the Society asking him to designate into which one of these two groups he believes he should be placed. (This method has been pursued by the Medical Service Administration of New Jersey)

To designate as specialists all those so certified by the specialty boards, those physicians who state that they limit their practice to a special field or who practice a specialty in an approved hospital as a member of that hospital's regular staff

With regard to the third question, again for the purposes only of facilitating discussion, the committee submits the following idea

That the schedule of fees approved by the Council on April 10, 1946, be regarded as specialists' fees and that, when the services called for in this schedule are rendered by general practitioners, the compensation shall be 20 per cent less than that set forth in that schedule. If the Council should adopt some such formula as this, it is necessary that the committee be allowed a leeway, not to exceed 5 per cent, so that the fees finally set down for the general practitioner shall appear in round numbers

The committee, in its report to the Council on April 20, 1946, recommended that the Blue Shield be the administrative agency in Massachusetts for the plan which concerned itself with the medical care by the civilian doctor of those for whom the Veterans Administration is responsible. The Council will remember that this type of administration was contrasted with that adopted by the Kansas State Medical Society. Under the latter plan, the Veterans Administration was its own administrative agent, the Society limiting itself to supplying the agency with a list of physicians willing to serve under schedule of fees agreed on and to maintain a close liaison with the Veterans Administration whereby the Administration would have the assistance of the Society in matters of dispute

The Council adopted this recommendation made by the committee. The committee now recommends that this action of the Council be rescinded

The committee is impelled to make this recommendation because of a distressing experience which the New Jersey Medical Service Corporation has had with an administrative plan similar to that approved by the Council on April 10, 1946

In the event that the Council adopts this recommendation, the committee will recommend the approval of the Kansas Plan modified so as to provide that the Blue Shield shall act as the liaison between the Veterans Administration and the physicians rendering the service in Massachusetts

In arriving at this latter recommendation the committee wishes to say that it has had only informal conversations with the Blue Shield on this subject.

The committee points out that until decisions are made with regard to these matters, its activities are at a standstill

HUMPHREY L. MCCARTHY, Chairman
JAMES K. BRAGGER
MICHAEL A. TIGHE

APPENDIX NO 6

REPORT OF THE COMMITTEE TO STUDY REVISION OF THE SALARIES OF THE EMPLOYEES OF THE SOCIETY

On May 21, 1946, a resolution was passed by the Council authorizing the President to appoint a special committee of three to study the matter of revision of the salaries of the employees of the Society and confer with the Committee on Finance. This committee was appointed and consists of Drs. Buck, Nye and Kickham

Your committee met and has given careful consideration to the subject matter as contained in the resolution. It was noted that there were three salaried employees and two officers of the Society who were compensated directly by the Society. Your committee in studying the matter weighed the fact that the employees of the Society are not beneficiaries under the Social Security Act and are not covered by any pension plan

Your committee is unanimous in the opinion that because of the increased cost of living, as indicated by all indices available, the compensation of the salaried employees of the Society who have been employed six months or more should

be increased by 20 per cent, retroactive to July 1, 1946 in the case of one employee who only recently joined the staff it is recommended to the proper committee that her salary be increased 20 per cent on January 1, 1947

Your committee also gave consideration to the compensation received by the two elected officers, namely, the Secretary and the Treasurer, whose compensation is paid by the Society. It is well recognized that the business and responsibilities of the Secretary have increased manifold in the last few years, and the same condition also prevails in the office of the Treasurer. In view of these facts, it is the considered opinion and recommendation of your committee that the compensation of the Secretary be increased from \$3,000 to \$4,000 per annum, and the compensation of the Treasurer be increased from \$2,000 to \$2,500 per annum, with increases retroactive to July 1, 1946

Your committee recommends that an extraordinary appropriation be made to cover this increased compensation for the period from July 1 to December 31, 1946, in the amount of \$1,332. The details of the recommended increases in compensation are as follows:

POSITION	PRESENT YEARLY COMPENSATION	RECOMMENDED YEARLY COMPENSATION	INCREASE IN 1946
Treasurer	\$2,000	\$2,500	\$250
Secretary	3,000	4,000	900
Executive Secretary	4,000	4,000	400
Miss Gaston	1,820	2,184	182
			\$1,332

These recommendations have been presented to the Committee on Finance, and have been approved by said committee.

APPENDIX NO 7

REPORT OF THE MASSACHUSETTS REPRESENTATIVES TO THE HOUSE OF DELEGATES OF THE AMERICAN MEDICAL ASSOCIATION JULY 1-5, 1946

I present this report as the senior member of your delegation attending the meeting of the House of Delegates in San Francisco from July 1 to 5, 1946. There was a full attendance, despite the distance and difficult travel conditions.

This marked the first time that the newly authorized Section on General Practice had its delegate sit in on the deliberations. In the assignment of the various reference committees your representatives fared well — Walter Phippen to the important Committee on Miscellaneous Business, Dwight O'Hara to Sections and Section Work, Leland McKinnick to Medical Education, and others of us to other committees. As I stated in my report of last December, we cannot give too much praise and appreciation to the tremendous amount of earnest and intelligent work performed by these reference committees. They are the works or machinery, and make possible the really large amount of work done. The addresses of President Lee, President-Elect Shuldene, and Speaker Fouts were all earnest, thoughtful and convincing, and on the usual high plane. These are all well worth reading and appear in the July 13 issue of the *Journal of the American Medical Association* (pages 905, 907 and 908).

The balloting for the Distinguished Service Award resulted in an overwhelming vote for the eminent physiologist from Chicago, A. J. Carlson, at the meeting held later on Tuesday evening he was given this award *in absentia*.

At this point one may mention Speaker Fouts, serving for the first time, he having been elected only last December at Chicago. He proved himself as able, efficient and eminently fair presiding officer. Speakers usually serve until they choose to resign, and this commonly is a matter of six or seven years (or more). He deserved re-election. California, however, had other ideas and proposed Dr. Goin, of Los Angeles, a most able man. The balloting resulted in the re-election of Fouts by the narrow margin of 90 to 77. California did not move to make it unanimous.

The usual long reports of the officers (Secretary, Treasurer and various councils) reading of the hills and report from the Washington office of the American Medical

Association, and the report of the Committee on Postwar Planning, filled up the morning of the first day. The details of all these reports should be read in the journals of July 6 and 20. They are much too long and detailed to lend themselves to easy summary. Also worth reading is the editorial on page 974 of the July 20 number.

On the afternoon of the first day, there were further long committee reports dealing particularly with rural medical service in the Middle West, Far West and South — the great open spaces. The usual amount of new business was offered and was referred to the various reference committees.

On the morning and afternoon of the second day, reports of the various reference committees were presented to be acted on then, or debated and referred back, a not uncommon procedure.

To show how deeply involved the American Medical Association is in industrial matters one should read the report of the Committee on Executive Session, with reference to the national bituminous wage agreements (pages 993, 994, 995 and 996 in the July 20 number of the *Journal of the American Medical Association*), which are of most vital importance in some parts of the country.

Wednesday, July 3, was an open date for the delegates except for the members of the various reference committees, there was no holiday for them. There was also no meeting of the delegates on Thursday morning.

On the afternoon of Thursday (the final day) all reference committees' reports, for the most part fairly long, were acted on, usually without much debate. Then came the reports of the chairman of the Board of Trustees, Dr. Sensenich, on the changes in organization of the American Medical Association in accordance with the recommendations of the Rich Public-Relations Report. This report had but just been received and was so long it could only be sketchily summarized. The following is essentially what transpired:

Changes in the organization of the American Medical Association in accord with the recommendations of the Rich Public Relations Report were approved by the House of Delegates.

The Bureau of Medical Economics is to be expanded with a leading economist employed to develop factual material in the field for use in the *Journal of the American Medical Association and Hygiene*.

The general manager is to have an executive assistant — an expert in the field of public relations — to interpret the activities of the various councils and bureaus to the public and medical profession.

The name of the Council on Medical Service and Public Relations was changed to the Council on Medical Service.

Although the title of the Council was shortened its field of operation and duties was enlarged. The Division of Prepayment Plans has definitely been placed under it, putting the Ten Point Program into actual practice is one of its major concerns. It will intensify its work in the field of professional relations extending the scope of the regional conferences and the "News Letters." The House of Delegates instructed it to develop the health-council idea and approved its recommendation for the creation of a speakers' bureau. The Washington office of the Council remains intact.

It was agreed that a special committee, not a reference committee, should be appointed to study, with the Trustees this Rich report before the next session of the House of Delegates and bring to its recommendations. I particularly call to your attention the minutes of the third meeting on Thursday afternoon (page 999 *et seq.*) dealing with legislation and public relations.

The election of officers concluded the meeting. Olin West for nearly twenty-five years the most efficient secretary of the American Medical Association, was unanimously elected president-elect. The affection and respect for this man among the delegates is difficult to express. He is most worthy of it. His remarks after the election are found on page 1004 of the July 20 number. These remarks were made entirely offhand, without notes, and clearly characterize the man and his ideals. They should be read.

The following are a few incidentals:

Hereafter there are to be two sessions a year of the House of Delegates, the mid-winter meeting to be held in Chicago.

The next meeting in 1947 (Centennial) is to be held in Atlantic City, 1948 in St. Louis, 1949 in New York City (provided the rates for the hiring of halls are not prohibitive)

A rising vote was called for on the Wagner-Murray-Dingell bill, it was unanimous. I observed no one sitting.

California and the San Francisco County Medical Society well deserve the hearty congratulations of the American Medical Association for their remarkable efficiency and open-handed generosity.

It was a good meeting, free from the element of pressure so noticeable last December at Chicago. It was felt certain that Congress would not act on the health bills this term, thereby giving the various voluntary prepayment methods a chance to get well under way.

DAVID D. SCANNELL

APPENDIX NO 8

COMMUNICATION

AMERICAN MEDICAL ASSOCIATION

535 North Dearborn Street, Chicago 10

August 9, 1946

Dr. Michael A. Tighe, Secretary
Massachusetts Medical Society
Boston, Massachusetts

Dear Dr. Tighe:

At the recent meeting of the House of Delegates of the American Medical Association in San Francisco, a proposed amendment to the by-laws was submitted by Dr. James C. Sargent, Wisconsin. This was referred to the Reference Committee on Amendments to the Constitution and By-Laws. Dr. Lowell S. Goin, California, chairman. The Reference Committee in its report on the proposed amendment recommended that it be not adopted and suggested instead the adoption of the following resolutions. The report of the Reference Committee, including the resolutions, was adopted. The resolutions are as follows:

RESOLVED, That it is a policy of the House of Delegates that resolutions should be introduced at least thirty days prior to any meeting of the House and be it further

RESOLVED, That such resolutions be published in the *Journal* and in the "Handbook of the House of Delegates," and be it further

RESOLVED, That the secretary of the Association be directed to write annually to the secretary of each constituent association requesting that all resolutions adopted by the said constituent association and requiring the attention of the House of Delegates of the American Medical Association be submitted to the secretary's

office as far in advance of the meeting of the House of Delegates as may be possible, and that the secretary request that the communication be read in the House of Delegates of each constituent association, and be it further

RESOLVED, That the secretary be directed and authorized to secure sufficient assistance to mimeograph all resolutions submitted in compliance with this request so that each delegate may have in his possession at the opening of the House of Delegates copies of the resolutions to be introduced at that time.

This is being brought to your attention as a result of the adoption of the resolution.

Very sincerely yours,

[Signed] GEORGE F. LULL, M.D.

GEORGE F. LULL, M.D.

Secretary and General Manager

APPENDIX NO 9

COMMUNICATION

FEDERAL SECURITY AGENCY

PROCUREMENT AND ASSIGNMENT SERVICE

Washington, June 10, 1946

Dr. Michael A. Tighe, Secretary
Massachusetts Medical Society
8 The Fenway, Boston, Massachusetts

Dear Dr. Tighe:

For practical purposes the functions of the Procurement and Assignment Service have been terminated and the activities of the several state offices brought to a close. The success of the program in meeting the needs of the armed forces without sacrificing the civilian population may be attributed directly to the patient and tireless devotion of many state committees and countless local advisers. Many of these committeemen and advisers are unknown to the Directing Board, except through the results of their efforts, and it would obviously not be practicable to undertake to communicate with them.

In a recent letter to each state chairman, I asked that the appreciation of the Directing Board be conveyed to all the state and local representatives whose full co-operation was essential to the ultimate achievement. The Directing Board at its final meeting on May 17, 1946, resolved that the untiring efforts, kind tolerance and successful accomplishment of these state committee members and local advisers be commended to the appropriate professional state society for suitable recognition by the society.

I hope you will draw this recommendation to the attention of your society, and that it will be disposed to afford some such recognition.

Sincerely yours,

[Signed] FRANK H. LARBY, M.D.

FRANK H. LARBY, M.D.

Chairman, Directing Board

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

BENJAMIN CASTLEMAN, M.D., *Associate Editor*

EDITH E. PARRIS, *Assistant Editor*

CASE 32501

PRESENTATION OF CASE

First admission A sixty-seven-year-old housewife entered the hospital because of a lesion on the left side of the tongue. Except for a blood pressure of 190 systolic, 110 diastolic, physical examination and routine blood studies were negative. The urine had a specific gravity of 1.004 and 1.007 and contained few to many white cells per high-power field; there was a ++ test for albumin and no sugar. An epidermoid carcinoma (Grade II) of the tongue was resected, and the patient was discharged on the tenth postoperative day.

Final admission (eight months later) After operation the patient was examined regularly in the Tumor Clinic. A month before admission lymph nodes were palpated in the submaxillary regions and in the left side of the neck. The patient had no other complaints. There was no history of systemic disease other than hypertension.

Physical examination disclosed a palpable lymph node in the floor of the mouth. Beneath the left sternomastoid muscle lay a movable hard mass measuring 3.5 x 2.5 cm. A loud systolic murmur was audible in the mitral area.

The temperature was 98.6°F, the pulse 80, and the respirations 18. The blood pressure was 220 systolic, 130 diastolic.

Examination of the blood showed a hemoglobin of 11 gm per 100 cc and a white-cell count of 8000. The specific gravity of the urine was usually below 1.010, but registered 1.020 on one occasion. Tests for albumin ranged from 0 to ++++. On admission the sugar reaction was orange. Many white cells per high-power field, often in clumps, were usually seen in the sediment. The fasting blood sugar was 286 mg and the nonprotein nitrogen 70 mg per 100 cc. In the x-ray films the heart was of normal size. An area of increased density extending from the left lateral chest wall had somewhat the appearance of an old infarct. An electrocardiogram was interpreted as representing left ventricular hypertrophy and strain.

During the preoperative course insulin was given. The blood sugar never fell below 220 mg per 100 cc,

but the urine tests remained green after the third day. With the administration of large amounts of fluid the nonprotein nitrogen stabilized between 60 and 70 mg per 100 cc. The cholesterol was 284 mg per 100 cc, and the chloride 98 milliequiv and the carbon dioxide 26 milliequiv per liter. A callus on the right foot infected with beta-hemolytic streptococci caused considerable local swelling for several days and was accompanied by a daily temperature of 100 to 101°F. From the eighth to the seventeenth day, 192,000 units of penicillin were given, and the drug was then discontinued. The temperature was normal from the fourteenth to the twentieth hospital day, when a radical dissection of the left side of the neck was carried out, with removal of several carcinomatous lymph nodes. On the following day the temperature rose to 102°F, the pulse and respirations were rapid. The blood sugar was 500 mg per 100 cc and ranged from 360 to 600 mg thereafter, despite dietary treatment and insulin. There were moist rales at both lung bases.

During the week following operation the temperature gradually fell to 100°F. The wound progressed satisfactorily, and the stitches were taken out on the twenty-eighth hospital day. There was a pocket of pus in its upper angle, from which a moderate number of colon bacilli and many colonies of *Staphylococcus aureus* were obtained on culture. Meanwhile, the nonprotein nitrogen had risen to 115 mg per 100 cc, and the chloride and carbon dioxide had fallen to 90 and 21 milliequiv per liter respectively. The patient was semistuporous, with fast, shallow respirations. A chest x-ray film was negative on the third postoperative day. By the tenth postoperative day the patient was in deep coma. Respirations were fast, shallow and gasping, and the nonprotein nitrogen had risen to 170 mg per 100 cc. Death occurred on the same day.

DIFFERENTIAL DIAGNOSIS

DR. WILLIAM BECKMAN: It is evident from the record that the patient had at least three diseases that are potentially fatal: carcinoma, diabetes and nephritis. The problem seems rather to decide which of these was the most important and what the relation was between any or all of them. We do not have any trouble making the diagnosis of carcinoma of the tongue because we are kindly told that it was present — there was pathologic evidence in both tongue and lymph nodes. I do not believe that carcinoma of the tongue is apt to metastasize far away from the local site, and I therefore doubt that metastasis was closely connected with this patient's death.

Either one or both of the other conditions mentioned are likelier causes. We can make a diagnosis of diabetes because we have the usual criteria for that diagnosis: a high fasting blood sugar, accompanied by sugar in the urine. By and large, when one thinks of diabetes one thinks of a condition

that is occasioned by an inadequate supply of insulin. The body cannot make enough insulin to supply its needs, but a high blood sugar and glycosuria occur in other conditions not due to insulin lack, such as obesity with diabetes, which clears up when the patient reduces, and intercapillary glomerulosclerosis, which is a special pathologic entity, with diabetes as an associated symptom. It is also an associated symptom in other conditions, such as Cushing's disease, in which it is not affected by the administration of insulin so much as it is in diseases in which insulin lack is the primary disturbance. I think that this diabetes fell into the type not affected by insulin, because the patient was given a great deal of it, although we do not know how much, but the blood sugar was never brought below 200 mg per 100 cc which is about twice normal according to our laboratory.

We are also able to make the definite diagnosis of nephritis of some sort. The patient had high blood pressure, albuminuria and an elevated nonprotein nitrogen in the serum. Those three things are sufficient to make the diagnosis of nephritis, although they do not help much in deciding the type. Apparently, there was pus in the urine, which suggests pyelonephritis. I think that this is the most frequent kind of nephritis in a patient of this age, although vascular nephritis is certainly a close second. There is little to suggest primary glomerulonephritis. In any event, the patient had severe chronic nephritis. She had a severe infection during the hospital stay, and it is well known that infection accentuates both diabetes and nephritis. The final episode was one of coma, which occurs both in diabetes and in the terminal stages of nephritis, so that it is important to differentiate them. It is quite improbable that the patient had diabetic acidosis because she did not have acetonuria and because the carbon dioxide content of the blood, although slightly reduced, was only 21 milliequiv per liter, which is the lower limit of normal and well out of the range of diabetic acidosis. I am therefore forced to the conclusion that the terminal episode was coma due to renal failure rather than to diabetes, this is further indicated by the marked rise in nonprotein nitrogen that occurred terminally. In such a situation, it is tempting to relate the two conditions, diabetes and nephritis, in terms of intercapillary glomerulosclerosis, but I do not see how that is possible on the basis of the information that is given. I hold to the principle that one cannot make the diagnosis of intercapillary glomerulosclerosis unless there are definite changes in the optical fundi—I used to believe that this was always true, but I was wrong. In one of these exercises, Dr Earle Chapman* discussed a case—without preparation, by the way—and correctly made the diagnosis of intercapillary glomerulo-

sclerosis on the basis of the association of diabetes and nephritis, in spite of the fact that the patient, whom I had taken care of during life, had normal fundi up to the time of death.

My diagnoses are cancer of the tongue, which presumably was not related to the terminal episode, diabetes, which did not produce the final coma, and chronic nephritis—presumably chronic pyelonephritis. I do not believe that I have enough evidence to make a diagnosis of intercapillary glomerulosclerosis.

DR REED HARWOOD: Was this patient given large doses of insulin?

DR BEVERLY TOWERY: Large doses were not given because the patient seemed to have a high penetration level for sugar. The dose was fairly low. The attempt was not made to get the blood sugar down much below 200 mg per 100 cc.

DR HARWOOD: After the operation did the blood sugar remain between 360 and 500 mg per 100 cc?

DR TOWERY: Yes. It brought up the question in our minds whether the patient had acute disease in the pancreas following operation as a result of which the insulin supply had been suddenly reduced. Whether that is true or not I do not know. On the day before death she received a total of about 60 units of insulin in divided doses.

DR HARWOOD: That is not a large dose for a person running such a high blood sugar.

CLINICAL DIAGNOSES

Uremia
Nephrosclerosis
Pyelonephritis
Diabetes
Hypertension
Arteriosclerotic heart disease

DR BECKMAN'S DIAGNOSES

Cancer of tongue, with local metastases
Chronic pyelonephritis, with uremia
Diabetes mellitus

ANATOMICAL DIAGNOSES

Acute coronary thrombosis, with cardiac infarction
Nephrosclerosis
Subacute pancreatitis, with fat necrosis
Chronic cholecystitis and cholelithiasis

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY: This patient was quite a museum of pathologic findings at autopsy. Dr Beckman was correct in his prediction that the carcinoma of the tongue had nothing directly to do with her death. There were only regional metastases in the cervical lymph nodes. There was no extensive carcinomatosis. The kidneys, which were rather small and contracted, showed on microscopic examination a severe grade of arteriosclerosis. I think that the involvement was advanced enough to make it quite reasonable to assume that the

*Case Records of the Massachusetts General Hospital (Case 30351).
New Eng J Med 231:333-337, 1944

patient died in uremia. There was another factor, however, that probably contributed to death and perhaps also to the renal insufficiency. There was a very large area of fresh infarction in the myocardium, with a thrombus of corresponding age in the left descending coronary artery. Sudden myocardial failure may have terminally increased the degree of renal failure.

The surprise of the autopsy was the pancreas. As soon as the abdomen was opened and the omentum reflected, it was noted that the undersurface of the omentum was dotted with yellowish cheesy areas. The pancreas itself was greatly enlarged, weighing about 400 gm, and was filled with yellow, cheesy masses. Grossly, no normal pancreatic tissue could be recognized, and microscopically only the smallest islets persisted here and there. It is tempting to assume that the diabetes was directly due to destruction of the pancreas. That is a relatively rare event. We see a great many cases of pancreatitis in which there is massive destruction of pancreas and in which no diabetes develops. On the other hand, there was no sugar in the urine during this patient's first hospital stay only eight months before the second entry, when she was proved to be severely diabetic. I therefore think that the evidence in this case is fairly good that pancreatic necrosis was the direct cause of the diabetes. As so often in pancreatitis, there was chronic infection of the gall bladder and cholelithiasis.

DR. TOWERY: How acute was the process in the pancreas?

DR. MALLORY: It was essentially old. There was nothing whatever in the clinical history, of course, from start to finish, to suggest an attack of acute pancreatitis, except perhaps the blood sugar.

DR. EDWARD BENEDICT: What would have happened if she had been given massive doses of insulin? Would she have improved?

DR. MALLORY: I think that she died of uremia, complicated by cardiac failure, and that neither the diabetes nor the cancer of the tongue was in any way responsible for death.

DR. BECKMAN: Would you not rather say that it was cardiac failure complicated by uremia, because of the fact that the nonprotein nitrogen rose so rapidly as a result of the congestive failure?

DR. MALLORY: That is a better way to put it. The lungs were markedly congested and edematous.

hot and cold sensations. Pain developed and became so intense that the patient was completely incapacitated. The most recent menstrual period had started six days before admission and was almost at an end. The patient had had intercourse before the onset of the period. There had been no intermenstrual bleeding or discharge. Periods occurred every twenty-eight days, lasting about a week. There had been no frequency, urgency, hematuria or dysuria.

Five years before admission the patient had had a ruptured ectopic pregnancy. Ten years earlier the appendix had been removed.

Physical examination revealed a healed midline, suprapubic scar and a right paramedian scar. The abdomen was soft, with tenderness above the pubis. There were no masses. Blood was trickling from the cervical canal. There was a feeling of fullness in the right vault. Motion of the cervix caused severe pain. Rectal examination was negative except for pain on motion of the cervix.

The temperature was 100°F, and the blood pressure was 100 systolic, 60 diastolic.

Examination of the blood disclosed a red-cell count of 4,200,000, with a hemoglobin of 10.0 gm, and a white-cell count of 11,500. The urine was normal. No gram-negative cocci were seen on vaginal smear.

After the patient had been put to bed the pain rapidly improved and subsided completely. She felt better, but there was suprapubic tenderness. About two hours after admission a slight, constant lower abdominal pain began and was accompanied by slight spasm in the right lower quadrant. Three and a half hours after admission the pain was again severe, and a mass was felt by pelvic examination to the right of the uterus. The white-cell count had risen to 13,700, with 84 per cent neutrophils.

An operation was performed half an hour later.

DIFFERENTIAL DIAGNOSIS

DR. FRANCIS M INGERSOLL: It is apparent from the history that an acute surgical emergency existed. A frequent condition that accounts for this type of history and physical findings is an ectopic pregnancy, which is suggested by certain outstanding findings in this case. First of all, the patient had a history of a previous ectopic pregnancy, and it is well known that a person who has had one ectopic pregnancy is liable to have a second. The suddenness of the onset of symptoms is also in favor of the diagnosis. The course in the hospital is not typical but fits in with what happens after an ectopic pregnancy ruptures. The lesion starts to bleed, the rupture seals off, the bleeding stops and on pelvic examination little is found. I remember a patient with ectopic pregnancy in whom examination failed to reveal bleeding. I told her to call me if anything happened. When I got home I had a

CASE 32502

PRESENTATION OF CASE

A twenty-seven-year-old married tripara, a nightclub singer, entered the hospital complaining of severe, continuous lower abdominal pain.

Three hours before admission an uneasy feeling had begun in the lower abdomen accompanied by

that is occasioned by an inadequate supply of insulin. The body cannot make enough insulin to supply its needs, but a high blood sugar and glycosuria occur in other conditions not due to insulin lack, such as obesity with diabetes, which clears up when the patient reduces, and intercapillary glomerulosclerosis, which is a special pathologic entity, with diabetes as an associated symptom. It is also an associated symptom in other conditions, such as Cushing's disease, in which it is not affected by the administration of insulin so much as it is in diseases in which insulin lack is the primary disturbance. I think that this diabetes fell into the type not affected by insulin, because the patient was given a great deal of it, although we do not know how much, but the blood sugar was never brought below 200 mg per 100 cc which is about twice normal according to our laboratory.

CONFUSION WORSE CONFOUNDED

THERE are some famous lines in *Paradise Lost*, describing the flight of Satan's band,

for such a numerous host
Fled not in silence through the frightened Deep,
With ruin upon ruin, rout on rout,
Confusion worse confounded,

that a year ago would have been considered particularly appropriate to the hosts, undoubtedly of evil, recently routed by the victorious United Nations, this year, although we are still certain of who was defeated, considerable doubt may be entertained regarding who is victor

Scarcely more than a year ago our own nation, despite some industrial unrest, was a unified, integrated machine set to produce a single result — the maintenance of national security against dangers from without. Each man was at work, but his labors were for a purpose: he could put his hand upon his neighbor's shoulder and call him comrade — they were working toward a common goal. "Sweet," wrote Shakespeare, "are the uses of adversity", we knew them then.

This year, frustration is in the atmosphere, we have no sun of York to shine on the winter of our discontent. Most of us are still hard at work, particularly the doctors of our acquaintance who meet no longer with a wartime forbearance on the part of a mutually striving clientele. But many are not working at all, a fumbling policy having put them on the dole, many veterans of all ages are unable again to become average citizens. Government control has broken down, and inflation is consuming reasonable profits. We are facing and failing to cope with materialism and moral disintegration within, and we are failing to accept world leadership without.

We are permitting the Great Patriot, the king of the coal fields, to hold his knife at the throats of a hundred and forty million Americans, mindless of the fact that the days of rugged individualism are over, and that no gain of great importance can be made by anyone without a co-operative effort on the part of those involved.

We are hard at work, — except for those who do not work at all, — but we are working without the solidarity that comes from working in a common cause. We have little patience with each other, we have lost our feeling of neighborliness. True, we share a common anxiety, but we are also victims of a common selfishness that will last until we again have a mutual goal to unite us in some constructive effort. That goal can consist of no material devices. Among ourselves and with the rest of the world, the most urgent issue on which to unite today is that of world peace. This is our desideratum. We shall not overcome our present insecurity until we can feel that we are striving, with other nations, for that end.

frantic telephone call saying that something had happened within ten minutes after I had left the patient's house. At operation she had a bleeding ectopic pregnancy. In the case, under discussion, the patient had first an indefinite and later a definite mass, probably due to further hemorrhage. Also, exquisite tenderness on motion of the cervix was noted on both vaginal and rectal examination. That is characteristic of an ectopic pregnancy. Motion of the cervix causes motion of the partially ruptured ectopic pregnancy, and pain is elicited. This sign is not confined to ectopic pregnancy, however, being found in twisted cyst of the ovary or pelvic inflammation.

The red-cell count was slightly low, but I do not believe that that is a help in the final diagnoses. If it had been markedly lowered, we should be more convinced that the patient was bleeding intraperitoneally. I do not believe that the patient had bled enough to lower the red-cell count markedly. The white-cell count is consistent with ectopic pregnancy.

A few facts are against the diagnosis of an ectopic pregnancy. First, the patient had not missed a period. We know, however, that patients can have perfectly normal periods with pregnancy in the tube or ovary. Secondly, the only intercourse mentioned was immediately prior to the onset of the last period, and this statement implies that there had been no other intercourse in recent weeks, so that she could not have been pregnant.

What other conditions are possible? Pelvic inflammation due to gonorrhea comes to mind. The acuteness of the onset of pain, the lack of spasm and the fact that no gonococci were found in the vagina make it unlikely that the patient had pelvic inflammation. A rare condition is torsion of a normal fallopian tube. Twisted ovarian cyst can give all the same symptoms and is a possibility in this case. Against it is the fact that no discrete mass was felt at the first examination. Another possibility is a ruptured ovarian cyst accounting for the severe pain and the physical findings described. That is unlikely, however, and in conclu-

sion I believe that this patient had an abdominal emergency that necessitated operation, and I believe that the most probable diagnosis is an ectopic pregnancy.

CLINICAL DIAGNOSIS

Twisted ovarian cyst?
Pelvic inflammatory disease?
Ectopic pregnancy?

DR INGERSOLL'S DIAGNOSIS

Ectopic pregnancy

ANATOMICAL DIAGNOSIS

Ectopic pregnancy

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY. At operation a hemorrhagic mass was found at the fimbriated end of the right tube, the left tube and ovaries having been resected previously, as the history stated. There was approximately 300 cc of blood in the abdomen. The tube was removed, the histologic examination showed numerous chorionic villi distributed in decidual tissue, a characteristic finding of tubal pregnancy.

DR GEORGE CLOWES. A few points of interest are not brought out in the record. When the patient first came in, the mass described in the pelvis was not palpable. Both vaults were felt to be clear. Then, with the recurrence of pain, she was again examined, and a mass was thought to be felt by one examiner, although another observer was not able to confirm it.

DR BEVERLY TOWERY. Did she have hemorrhage into the broad ligament?

DR CLOWES. The blood was free in the peritoneal cavity, and there was no hemorrhage in the broad ligament.

DR HOWARD ULFELDER. What was the duration of the pregnancy?

DR MALLORY. I was trying to guess that. It could have been two weeks, although I am inclined to believe that it was longer than that.

NECROTIZING RENAL PAPILLITIS A FORM OF ACUTE PYELONEPHRITIS

STANLEY L. ROBBINS, M.D.,* G. KENNETH MALLORY, M.D.,† and THOMAS D. KINNEY, M.D.‡

BOSTON

NECROSIS of the renal papillae, sometimes termed "papillitis necroticans"¹ or "necrotizing pyelonephritis,"² is an infrequently recognized and severe type of suppurative renal infection that is usually encountered in diabetic patients although it is occasionally found in nondiabetic persons.^{3, 4} The lesion, which has been a well recognized pathologic entity for many years, was recently well described by Günther.⁵ It remains, however, a poorly defined clinical entity that is usually found as an unexpected lesion at autopsy. Recent publications emphasize the fact that the problem of acute pyelonephritis—in particular that of necrotizing papillitis—is of greater magnitude than its obscurity indicates. In 1942 Harrison and Bailey² clearly demonstrated that infections of the urinary tract in diabetes are not only frequent but also usually asymptomatic of 50 diabetic patients studied, 27 had bacteria in the urine on a direct smear examination of the sediment and 10 showed completely unsuspected pyuria. In contrast, only 4 control patients out of 50 had bacteriuria, 2 of them had associated pyuria. These results suggest that latent infections of the urinary tract are extremely frequent in diabetic patients and in many cases may serve as foci for the development of the severer lesions under discussion. That these infections are not merely potential hazards is borne out by the fact that 67 per cent of the diabetic patients on whom autopsies were performed at the Mallory Institute of Pathology from 1933 to 1942 died chiefly as a result of acute pyelonephritis.⁶ Significantly, most of this group had necrotizing papillitis.

During the years 1932 to 1945, post-mortem examination disclosed 26 cases of this lesion at the Mallory Institute of Pathology, Boston City Hospital, and at the Peter Bent Brigham Hospital, 19 of which occurred in diabetic and the remaining 7 in nondiabetic patients.

This paper presents a clinical and pathologic analysis of this series of diabetic and nondiabetic patients who at autopsy were found to have necrosis of the renal papillae. With continued study of anatomically verified cases, it is to be hoped that the clinical picture of this syndrome will become established as a clearly defined entity.

On review of the series of cases under discussion it at once became apparent that they tended to assume one of several clinicopathologic patterns that recurred with remarkable constancy throughout the series. The following representative cases have been selected for citation.

CASE 1. S. F. (B.C.H. 1,160,583), a 61-year-old woman, entered the hospital with the complaint of a red, tender, swollen left lower leg. She had stumbled against a chair 6 days before entry, injuring the leg, and since that time the discomfort and swelling had been steadily progressive despite local applications of heat. She was known to have had diabetes for "many years," which had apparently been controlled by a diet supplemented with 8 units of regular insulin daily. There was no history of previous infections or diabetic accidents.

Physical examination disclosed a well oriented patient in no obvious distress. The only finding of significance was the presence of a fluctuant, red area of marked tenderness over the lateral aspect of the distal left lower half of the leg.

Examination of the urine showed a trace of albumin, a green to orange Benedict reaction and a rare white cell per high-power field. The fasting blood sugar varied between 229 and 418 mg per 100 cc. The serum nonprotein nitrogen was 39 mg per 100 cc on admission.

The fluctuant area of the left lower leg was incised, and *Staphylococcus aureus* was cultured from the pus. Sulfadiazine and penicillin in full dosages were administered, and the temperature soon became normal and the incised wounds appeared to be slowly healing. The diabetes mellitus was well controlled with 20 units of regular insulin daily. After 2 weeks of apparent improvement, however, the temperature began to swing from 101 to 102°F. The urine contained innumerable white cells despite all medication, and the patient ran a severely septic febrile course terminating in stupor, coma and death during the 6th hospital week. A hemolytic *Staph. aureus* was cultured from the blood.

Autopsy. On gross examination the kidneys were enlarged, their combined weight was 300 gm. The capsular surfaces were free from cortical abscesses. On section several large, triangular areas including the entire tips of some of the papillae in each kidney were yellow green and completely necrotic. Several discrete abscesses, 0.2 to 0.3 cm in diameter, were present at the corticomedullary junction above these areas of papillary necrosis. The only other significant findings were a healing abscess over the left ankle.

AN EYE FOR AN EYE

THE Massachusetts Eye and Ear Infirmary has laudably set up what is known as "The New England Eye Bank" which is affiliated with the Eye Bank for Sight Restoration, Incorporated, of New York City. In the minds of certain lay persons, however, there are two misconceptions regarding it. In the first place, there is the erroneous idea that *any* type of blindness can be cured by the substitution of a donor's eye. Secondly, it is rather widely believed that if an eye is not used within seventy-two hours it is completely wasted.

There is only one type of blindness that can be cured or improved in this manner, namely, that due to corneal opacities. Of the approximately 250,000 blind persons in this country, approximately 15,000 are blind because of corneal opacities. The latter stand a good chance of having their sight restored or improved by a corneal transplant from an eye removed within one hour of death and used within seventy-two hours. Although the group represents only a small percentage of those who are blind, the possibilities for beneficial results are impressive.

If the eye is not used within seventy-two hours, is it wasted? By no means. The eyes of mammals other than man are not entirely satisfactory for histologic, anatomic and physiologic studies, and yet such investigations must be carried out if the human race is to benefit. An intact human eye that could not be used for a corneal transplant might be ideal for certain studies, since it is presumably free from major defects and clearly has the properties common to other human eyes, except, of course, lack of circulation. Another important use for these eyes would be the training of ophthalmic residents in surgical procedures. This would be far superior to the present custom of employing animal eyes.

If these two misconceptions could be cleared up in the lay mind, the Eye Bank at the Massachusetts Eye and Ear Infirmary would probably prosper even better than it now does.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

BURGER — Franklin D. Burger, M.D., of Wellesley Hills, died November 25. He was in his forty-seventh year.

Dr. Burger received his degree from University of Michigan Medical School in 1936.
His widow survives.

SYLVESTER — Albion W. Sylvester, M.D., of Pittsfield, died June 20. He was in his eighty-fourth year.
Dr. Sylvester received his degree from Bowdoin Medical College in 1892.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

ANTIPNEUMOCOCCUS SERUM FOR SEVERE PNEUMOCOCCAL INFECTIONS

Occasional requests are still received by the Department of Public Health for antipneumococcus serum. Most of these relate to cases of pneumococcal meningitis, a disease with such a high fatality rate, even under optimal conditions, that serum is generally regarded as an imperative adjunct to chemotherapy. The department will therefore continue to furnish antipneumococcus serum until such time as serum has been found to be superfluous in the treatment of severe pneumococcal infections.

Because of the small number of requests, all serum depots have been discontinued except the one at the Bacteriological Laboratory, State House, where 100,000-unit vials of Types 1 to 33, inclusive, are kept available. The issue of serum will continue to be based on the following provisions:

The pneumococcus must be typed in a laboratory approved for this diagnostic procedure by the Department of Public Health or in a federal laboratory.

The patient must be suffering from pneumococcal pneumonia, septicemia, endocarditis, meningitis or peritonitis.

Serums for Types 1, 2, 4, 5, 7, 8, 9, 14 and 18 will be furnished for treatment of the above conditions on type identification of the pneumococcus, regardless of whether it has been isolated from the sputum, throat or elsewhere.

Serums for other types will be furnished only when the organism is found in the blood, cerebrospinal fluid or peritoneal fluid.

Unused serum must be properly refrigerated and returned as promptly as possible to the Division of Biologic Laboratories, 375 South Street, Jamaica Plain 30.

When the patient is discharged, a case history on the form provided must be filled out and sent to the Division of Biologic Laboratories.

CORRESPONDENCE

RESTORATION OF LICENSE

To the Editor: At the meeting of the Board of Registration in Medicine held November 22, it was voted to restore the certificate of registration of Dr. Theodore Rosen, formerly of 45 Joy Street, Boston.

State House
Boston

NOTICES

ANNOUNCEMENTS

Dr. Hugh C. Donahue calls attention to the omission of his office address and telephone number from the current telephone directory. His office continues to be at 520 Commonwealth Avenue, Boston, and the telephone number is COM monwealth 2010.

Dr. William T. Haley, Jr., who has returned from military service, announces the opening of his office for the general practice of medicine at 79 Pleasant Street, Marblehead.

(Notices continued on page xvii)

weak and scanty. The blood pressure gradually fell to 80/40. Despite sulfonamide medication the temperature continued to fluctuate between 99.5 and 101°F. The serum nonprotein nitrogen rose to 264 mg per 100 cc. The patient's breathing became stertorous and labored, and he lapsed into coma and died on the 8th hospital day.

Autopsy. On gross examination the combined weight of the kidneys was 650 gm. The cortices were studded with abscesses, 0.1 to 0.5 cm in diameter, and in several areas pus had accumulated beneath the capsule in amounts up to 10 cc. On section, similar abscesses were seen scattered throughout the parenchyma, but in addition two or three papillae of each kidney were replaced near their tips by soft, yellow-green areas of necrosis. The prostate was bilaterally enlarged to approximately twice its normal size, and in the mid-

PATHOLOGIC ANATOMY

The gross and microscopic pictures of this lesion are remarkably constant, varying only in degree according to the stage it has reached when seen. The findings are not influenced essentially by different etiologic organisms and show no difference in the diabetic and nondiabetic groups.

Grossly, the earliest stage consists of scattered small abscesses located in the renal pyramid, more or less in a line parallel to the cortex at a level about

FIGURE 1 Photomicrograph of Early Lesion of Pyramid

there was a 1-cm ball-valve-like projection from the median bar obstructing the neck of the urethra. Serial sections of the prostate revealed several 0.5-cm areas of abscess formation. Bacteriologic examination was somewhat unsatisfactory, since cultures of the spleen, prostate and kidney obtained *Proteus vulgaris* that overspread the culture plates and masked all other growth.

The anatomical diagnoses were acute pyelonephritis, with encroaching papillitis, benign prostatic hypertrophy, acute and chronic prostatitis and hypertensive and arteriosclerotic heart disease, with decompensation.

This patient represented one of the nondiabetic patients who, in the wake of urinary-tract obstruction, developed an acute renal infection. The strategically located necrosis of the papillae superimposed on the fairly widespread cortical damage sufficed to produce acute renal failure, uremia and death in the relatively short time of eight days.

two thirds the way from the tip of the papilla to the junction of the pyramid and the cortex (Fig. 1). As the lesion progresses, these abscesses become confluent, resulting in a complete necrosis of the terminal two thirds of the pyramid. The appearance of the necrotic tissue is somewhat similar to that of an infarct of the cortex, except that it is apt to be yellow brown or yellow green, with the periphery sharply demarcated by a narrow zone of paler yellow-to-green tissue, which in turn may be surrounded by a border of reddish congestion. Varying amounts of the more usual type of acute pyelonephritis are found in the cortex of these kidneys. The process is frequently but not always bilateral, and in most cases all pyramids of the affected kidney are involved (Fig. 2).

and a fluctuant abscess, measuring 60 x 40 x 20 cm, in the left popliteal space. Hemolytic *Staph aureus* was cultured from both the blood and the kidneys.

The anatomical diagnoses were diabetes mellitus, as evidenced by the clinical findings and glycogen nephrosis, acute pyelonephritis, with necrotizing papillitis, a healing abscess over the left ankle and an abscess in the left popliteal space.

This case represented the insidious onset, in a diabetic patient, of renal infection secondary to focal infection elsewhere in the body. Death was attributed to a combination of severe infections of the leg and kidneys, neither of which alone could be considered as a fatal disease.

CASE 2 B C (BCH 1,161,259), a 68-year-old woman, entered the hospital with a left hemiplegia. Eight days previously she had experienced the sudden onset of transient left facial weakness and difficulty in talking. Several similar episodes occurred in the next few days. The patient sought hospitalization for relief of the complete unilateral paralysis. She was known to have had diabetes for 15 years, which had been controlled by diet alone.

Physical examination revealed an obese, flushed, restless woman with an obvious left hemiplegia. The lungs contained scattered moist rales posteriorly with bronchial breathing. Except for slight enlargement to the left, the heart was not remarkable. No signs of any infection, renal or otherwise, were demonstrable.

Examination of the urine demonstrated a trace of albumin and a green Benedict reaction. The fasting blood sugar was 196 to 270 mg per 100 cc. The serum nonprotein nitrogen was 42 mg per 100 cc on admission.

Soon after entry it became apparent that the left hemiplegia was of secondary importance to a rapidly developing urinary infection. *Klebsiella pneumoniae* (Type B) was cultured from the urine. The serum nonprotein nitrogen rose progressively to over 100 mg per 100 cc. Blood cultures, which at first were sterile, soon became positive for *K pneumoniae*. The temperature rose to 103°F. Various sulfonamides were administered without effect. The urinary output began to fail, and the patient lapsed into coma and died.

Autopsy On gross examination the combined weight of the kidneys was 330 gm. The cortical surfaces were studded with minute abscesses, 0.2 to 0.3 cm in diameter. On section of both kidneys most of the papillae were completely replaced by green, semifluid areas of necrosis. These areas were roughly wedge shaped, with their bases at the corticomedullary junction. The calyces and pelvises were filled with mucoid, green exudate. The brain showed moderate arteriosclerosis of the cerebral vessels, with thrombosis of the right middle cerebral artery and infarction of the right frontal, parietal and temporal lobes. Other pertinent findings were bilateral lower-lobe bronchopneumonia and an early adenocarcinoma of the colon. *K pneumoniae* was cultured from the heart's blood, kidneys and lungs.

The anatomical diagnoses were acute pyelonephritis, with necrotizing papillitis, diabetes mellitus (clinical), cerebral thrombosis, with encephalomalacia, of the right frontal, parietal and temporal lobes, bilateral bronchopneumonia of the lower lobes and carcinoma of the colon.

This elderly woman was admitted to the hospital after an obvious right cerebral vascular accident with evidence of a developing urinary-tract infection with *K pneumoniae* (Type B) and no other demonstrable focus of infection. In the course of seven weeks, the serum nonprotein nitrogen rose to over 100 mg per 100 cc. The patient became anuric and died in uremia. The urinary-tract infection apparently developed in the absence of any demonstrable focus of infection.

CASE 3 J G (BCH 1,164,454), a 55-year-old man, was admitted to the hospital in a state of stupor. The history obtained from his wife indicated that he had developed a "cold" 2 weeks before entry and had subsequently suffered

from a cough with occasional bouts of feverishness followed by shaking chills. No past or present history referable to diabetes mellitus was obtained.

Physical examination disclosed a moderately cyanotic man who was obviously extremely ill, was only garbled, inarticulate words. A few fine, moist wheezes were heard over the lung posteriorly. The heart was slightly enlarged, and there was a Grade II systolic murmur over the apex. There was no costovertebral-angle tenderness.

Examination of the urine showed a green Benedict reaction, no albumin was demonstrated despite the finding of 50 to 100 white cells per high-power field. The fasting blood sugar was 286 mg, and the serum nonprotein nitrogen 67 mg per 100 cc.

On the 2nd hospital day petechiae were noted over the extremities, the temperature rose to 106°F, and the respirations became labored. A beta-hemolytic streptococcus was isolated from the blood. The serum nonprotein nitrogen was 92 mg, and the fasting blood sugar 475 mg per 100 cc. Despite penicillin and sulfonamide the temperature remained elevated. The patient became anuric, the blood pressure dropped to 80/0, and he expired 70 hours after admission.

Autopsy On gross examination the combined weight of the kidneys was 630 gm. The capsular surfaces were relatively smooth and uniformly red brown, and there were no abscesses. On section there were numerous areas of yellow-white, puriform necrosis within the pyramids, involving almost all the papillae and in some extending from the cortex to the tip of the papilla. The medullary zones of the adrenal glands were red and hemorrhagic. The lungs and heart were essentially normal. The liver weighed 2750 gm and showed a diffuse yellow-brown nodularity, with many individual nodules up to 1 cm in diameter, section of the liver showed the parenchyma to be traversed by fine fibrous trabeculae. The spleen was enlarged, weighing 560 gm, but was otherwise not remarkable. A streptococcus with alpha to beta hemolysis was cultured from the heart's blood and kidneys.

The anatomical diagnoses were diabetes mellitus, as evidenced by the clinical findings and glycogen nephrosis, acute pyelonephritis, with necrotizing papillitis, and alcoholic cirrhosis of the liver.

This case, which occurred in a previously unsuspected diabetic patient, represented the disease in one of its most fulminating forms, the marked febrile illness and septicemia having had their origin in the renal infection. Petechiae of the skin, as well as adrenal medullary hemorrhages, simulating the Waterhouse-Friderichsen syndrome, were present. No other focus of infection was demonstrated at autopsy, and the renal lesion was the chief cause of both the clinical picture and death.

CASE 4 J R (BCH 1,058,331), a 68-year-old man, was admitted to the hospital for the second time within a period of 5 days because of acute urinary retention. On the previous admission he had also entered for acute retention, but had refused operation for removal of an obstructing prostate and had left the hospital against advice. He remained at home during this interval with no urinary difficulty until the day of re-entry. He stated that the first urinary symptoms had begun 4 months before admission. There was no history indicative of diabetes mellitus.

Physical examination revealed an elderly man lying quietly in no distress. The lungs were clear and resonant throughout. Examination of the heart revealed slight enlargement in the left, with an irregularity suggesting auricular fibrillation. The urinary bladder was palpated at the level of the umbilicus, and on rectal examination the prostate was large, symmetrical and firm.

Examination of the urine demonstrated a trace of albumin, no sugar and many white cells per high-power field. The serum nonprotein nitrogen was 59 mg, and the fasting blood sugar 108 mg per 100 cc.

After catheterization the patient appeared to be comfortable and well until the 2nd hospital day, when the temperature suddenly rose to 101°F and he became somewhat stuporous and disoriented. The urine, which had been fairly clear and adequate in amount on entry, became foul smelling

DISCUSSION

The most striking feature of necrotizing pyelonephritis is its frequent association with diabetes mellitus, in this series of 26 autopsied cases, 19 patients were diabetic. This distribution assumes even greater significance when it is realized that during this period of study approximately 10,000 autopsies were performed in these laboratories, of which approximately only 400 were performed on diabetic patients. It is essential, however, to emphasize the fact that although the disease is more characteristic of diabetic patients, it is also found in those without diabetes. Since the clinical features of the two groups differ somewhat, they are discussed separately.

In diabetes mellitus, acute pyelonephritis is a frequent complication, occurring in 60 patients in a series of approximately 307 diabetic patients who were autopsied at one of these laboratories.⁶ Necrotizing papillitis was present in 16 of these 60 cases.

the lesion developed post partum, so that no age group is immune to this disease. In the diabetic group women outnumber men 12 to 7.

The clinical courses appeared to assume one of two relatively constant patterns, which for the purposes of discussion can be categorized as "acute fulminating" and "subacute protracted." Patients in the former group frequently entered the hospital seriously ill with a sudden onset of symptoms suggestive of a severe generalized systemic infection. A rapidly fatal course developed, characterized by prostration, spiking, high temperature, rapid pulse and occasionally leukocytosis in the complete absence of clinically demonstrable foci of infection. Invariably marked pyuria and oliguria were present with associated azotemia. Most of these patients died within a period of days, one within four days of the onset of the illness. Death resulted either from uremia or from overwhelming infection. One patient suffered from systemic infection of such

FIGURE 3 Photomicrograph of Cortex and Pyramid, Showing the Distribution of a Well Developed Lesion

of acute pyelonephritis, producing the rough proportion in diabetic patients of 1 case of necrotizing pyelonephritis to every 4 of acute suppuration of the kidney. In terms of the frequency with which necrosis of the renal papillae is found in post-mortem examination of diabetic patients, the incidence is approximately 4.5 per cent. Some of the significant features of these cases, both clinical and pathological, have been summarized in Tables 1 and 2.

It is apparent that this lesion was found in diabetic patients of nearly every age group, the youngest patient being thirty-nine and the oldest eighty-one years old. The decade in which this pathologic entity was encountered most frequently in our series, however, was the seventh. Sheehan⁷ reported a case in an eighteen-year-old girl in which

severity that clinically the case was first thought to be acute bacterial endocarditis with petechial skin lesions, adrenal medullary hemorrhages were demonstrated at post-mortem examination.

In the "subacute protracted" cases there was usually a period of weeks and months of pyuria and obvious acute pyelonephritis, during which the disease appeared to undergo remissions and exacerbations. Invariably the patient's condition suddenly became critical, the pyuria growing more marked, and the disease followed a course resembling the acute type, progressing rapidly to a fatal termination. After pathological study of the kidneys in these cases, it seems possible to explain this course of events as one in which necrotizing papillitis was superimposed on a pre-existing nonspecific acute

In more advanced lesions portions of the involved papillae break off into the lumen of the pelvis, and complete sequestration may occur with sloughing of the whole papilla into the pelvis. If such a stage is reached during life, a fairly characteristic deformity of the pelvis can be seen on pyelography.

As would be expected from this gross description, the histology also varies with the age of the lesion. The earliest stage, as seen in the experimental pyelonephritis of the rabbit, consists in clumps of organisms in the interstitial tissue that provoke a

the pyramid consists of arterial capillaries lead down and venous capillaries leading up the pyramid with only poor anastomotic connections. It is probable that as a result of inflammation the afferent blood supply is greatly hindered, with consequent infarction.

In the well developed lesion the papillae are completely involved (Fig 3). At the base of the pyramid there is a zone composed of masses of organisms lying in capillaries, tubules, lumens and interstitial tissue and surrounded by large numbers of polymorphonuclear leukocytes. In this zone, scattered

FIGURE 2 Gross Appearance of Sectioned Kidney of a Diabetic Patient, Showing Well Advanced, Typical Pyramidal Lesions

polymorphonuclear leukocytic reaction, with necrosis and eventual rupture into the nearby tubules. In human beings probably the majority of abscesses start in a similar manner in the interstitial tissue, but the possibility that they may begin in the lumens of the tubules cannot be ruled out.

As the abscesses enlarge, or if two or more become confluent, a small area of infarct necrosis is likely to develop in the region below—that is, distal to the area involved—and to spread almost to the tip of the papilla. This is probably best explained by the circulation of the pyramid. In a normal kidney no blood vessels larger than capillaries are found in the distal two thirds of the pyramid, and apparently the entire blood supply of

capillaries contain fibrin thrombi and above this area the capillaries are found to be dilated and engorged. A similar zone of inflammatory infiltration—but without organisms or capillary thrombi—often extends around the complete periphery of the involved pyramid. The central portions of the papilla show infarct necrosis with pyknosis or loss of cell nuclei but maintenance of normal architecture, and there is little or no inflammatory infiltration. The further evolution of the lesion consists merely of a loss or disappearance of the necrotic tissue, only the zone of infiltrated tissue remaining near the base of the pyramid.

To date the healed stage, if healing does occur, has not been recognized.

Discussion

The most striking feature of necrotizing pyelonephritis is its frequent association with diabetes mellitus, in this series of 26 autopsied cases, 19 patients were diabetic. This distribution assumes even greater significance when it is realized that during this period of study approximately 10,000 autopsies were performed in these laboratories, of which approximately only 400 were performed on diabetic patients. It is essential, however, to emphasize the fact that although the disease is more characteristic of diabetic patients, it is also found in those without diabetes. Since the clinical features of the two groups differ somewhat, they are discussed separately.

In diabetes mellitus, acute pyelonephritis is a frequent complication, occurring in 60 patients in a series of approximately 307 diabetic patients who were autopsied at one of these laboratories.⁶ Necrotizing papillitis was present in 16 of these 60 cases

the lesion developed post partum, so that no age group is immune to this disease. In the diabetic group women outnumber men 12 to 7.

The clinical courses appeared to assume one of two relatively constant patterns, which for the purposes of discussion can be categorized as "acute fulminating" and "subacute protracted." Patients in the former group frequently entered the hospital seriously ill with a sudden onset of symptoms suggestive of a severe generalized systemic infection. A rapidly fatal course developed, characterized by prostration, spiking, high temperature, rapid pulse and occasionally leukocytosis in the complete absence of clinically demonstrable foci of infection. Invariably marked pyuria and oliguria were present with associated azotemia. Most of these patients died within a period of days, one within four days of the onset of the illness. Death resulted either from uremia or from overwhelming infection. One patient suffered from systemic infection of such

FIGURE 3 Photomicrograph of Cortex and Pyramid, Showing the Distribution of a Well Developed Lesion

of acute pyelonephritis, producing the rough proportion in diabetic patients of 1 case of necrotizing pyelonephritis to every 4 of acute suppuration of the kidney. In terms of the frequency with which necrosis of the renal papillae is found in post-mortem examination of diabetic patients, the incidence is approximately 4.5 per cent. Some of the significant features of these cases, both clinical and pathological, have been summarized in Tables 1 and 2.

It is apparent that this lesion was found in diabetic patients of nearly every age group, the youngest patient being thirty-nine and the oldest eighty-one years old. The decade in which this pathologic entity was encountered most frequently in our series, however, was the seventh. Sheehan⁷ reported a case in an eighteen-year-old girl in which

severity that clinically the case was first thought to be acute bacterial endocarditis with petechial skin lesions, adrenal medullary hemorrhages were demonstrated at post-mortem examination.

In the "subacute protracted" cases there was usually a period of weeks and months of pyuria and obvious acute pyelonephritis, during which the disease appeared to undergo remissions and exacerbations. Invariably the patient's condition suddenly became critical, the pyuria growing more marked, and the disease followed a course resembling the acute type, progressing rapidly to a fatal termination. After pathological study of the kidneys in these cases, it seems possible to explain this course of events as one in which necrotizing papillitis was superimposed on a pre-existing nonspecific acute

TABLE 1 Data in 19 Diabetic Patients with Necrotizing Papillitis

pyelonephritis as an apparently terminal complication coinciding with the sudden increase in the gravity of the clinical picture. This lesion did not lead to death in every case, since 5 patients died of unrelated causes (Table 1). Moreover, 2 diabetic patients were studied in each of whom a kidney showing necrotizing pyelonephritis was removed. Both progressed well postoperatively and were apparently free of renal disease a year later. Whether these cases represent examples of extremely rare unilateral necrotizing pyelonephritis in diabetic

This was borne out by the fact that the diabetes present in several of the patients in this series was so mild that it was controlled by diet alone.

Necrotizing papillitis was also present in 7 patients who did not have diabetes. All these patients were men between the ages of sixty-one and seventy-one (Table 2).

The small number of nondiabetic patients with necrosis of the renal papillae, despite the large number of autopsies performed on nondiabetic patients (in the neighborhood of 10,000), is in keeping with

TABLE 2 Data in 7 Nondiabetic Patients with Necrotizing Papillitis

PATIENT	AGE	SEX	EXTRA-RENAL INFECTION	DURATION OF PYURIA	CLINICAL EVIDENCE OF UAEMIA	ANTE-MORTEM BLOOD CULTURE	ANTE-MORTEM URINE CULTURE	POST-MORTEM KIDNEY CULTURE	COMBINED WEIGHT OF KIDNEYS	URINARY-TRACT OBSTRUCTION	CAUSE OF DEATH

patients is uncertain, but it is probable. The likelihood that the remaining kidney was involved to an equally severe extent and then healed to give adequate renal function alone appears to be remote, for reasons discussed below.

Not one of the cases studied presented any signs or symptoms referable to urinary-tract obstruction, partial or complete—a finding corroborated by pathological examination. This absence of urinary-tract stasis stands out in sharp contrast to the findings in the nondiabetic patients, most of whom had some symptoms referable to urinary-tract obstruction, usually those of prostatic enlargement.

The degree of severity of the diabetes did not appear to be a factor in the pathogenesis of the lesion.

The rarity of this lesion in patients without diabetes. During the period of study in which 7 typical examples of papillary necrosis were found, 93 cases of fairly marked, significant amounts of nonspecific acute pyelonephritis were encountered. The advanced age of these patients, as well as the striking dominance of the male sex, is closely related to the fact that the urinary-tract obstruction that frequently underlies these cases is almost invariably due to an obstructing prostate. It is interesting to note that necrosis of the renal papillae has been reproduced experimentally by Mallory et al.⁷ in nondiabetic rabbits by the ligation of one ureter and intravenous injection of organisms. In the non-obstructed kidney no significant lesions developed,

in the obstructed kidney an acute pyelonephritis with necrosis of the renal papillae, as well as cortical abscesses, was found — the exact analogue of the lesion found in the nondiabetic group discussed above, in which the necrotizing papillitis proved to be the cause of death, leading to a rapidly rising nonprotein nitrogen, terminal anuria with uremia.

Considering the series once again as a whole, including both diabetic and nondiabetic patients, it is apparent that in 20 out of the 26 cases at autopsy (Tables 1 and 2), death was directly attributable to the development of the papillitis, representing a mortality rate of 74 per cent, the proportion of deaths being equally divided between the diabetic and the nondiabetic patients.

It became apparent on the review of the clinical material that correct diagnosis of this type of renal lesion was rarely made before death. In only 1 case was the pyramidal, necrotizing character of the renal infection suspected prior to death, although in many cases, chiefly in the more protracted ones, the obvious urinary-tract infection was well recognized and under active therapy. The acute fulminating cases created the most confusing diagnostic problems, and such divergent diagnoses as bacterial endocarditis, perinephric abscess and pneumonia were made.

Clinically, this lesion should be suspected in any severe, acute infection of the urinary tract in both diabetic and nondiabetic patients with urinary obstruction, especially if there is an associated oliguria and rapidly rising nonprotein nitrogen. In suspected cases a retrograde pyelogram may demonstrate an irregular filling defect of the renal calyces that is due to necrosis and sloughing of the tips of the papillae.⁸ The changes in the pyelograms are not unlike those seen in renal tuberculosis.

Despite the high mortality in these cases, the correct ante-mortem diagnosis is of more than academic interest, since the lesion has two characteristics that dictate specific therapy. It is a suddenly developing and rapidly progressing, necrotizing bacterial lesion that must be treated not only actively but without delay. In addition, the strategic necrosis of the tips of the papillae impairing the urinary drainage of the associated nephrons may create a significant hazard to the use of sulfonamide compounds with their known tendency to precipitate out in the renal tubule under conditions of urinary stasis.⁹

It is to be stressed that necrotizing papillitis is simply a form of acute pyelonephritis in which the chief damage occurs within the pyramids, frequently destroying, in the severer cases, practically every pyramid. These areas of medullary necrosis are usually, but not invariably, found together with abscess formation within the cortex.

In the sections of the kidney lesions studied, as well as in all the cases that have come under study at these laboratories, no recognizable chronic or

healed papillary necrosis has been encountered. This fact leads to the conclusion that the cases either are invariably fatal or would have been if death had not been intercurrent. The failure to encounter a chronic or healing lesion makes it unlikely that this disease can heal. For these reasons, the 2 nephrectomized patients in whom papillary necrosis was found in the removed kidneys were thought to represent unilateral involvement. All the papillary lesions examined histologically were acute and sometimes were found in the presence of chronic nonspecific pyelonephritis, indicating that the papillary necrosis was preceded by the cortical changes and probably represented a superimposed terminal complication.

As can be seen from the tables, a great variety of bacterial agents were isolated in these cases, *Staph aureus*, *Escherichia coli*, *K pneumoniae* and *Streptococcus viridans* being the most frequent. It is, however, almost possible to predict the type of organism that will be found by an analysis of the clinical course of the case. Patients who entered with obvious foci of infection outside the kidney almost invariably developed staphylococcal and streptococcal renal infections, and in those in whom no definite preceding infection could be demonstrated the organisms cultured from the kidney were usually *Esch coli* and *K pneumoniae*. In many cases, however, mixed bacterial infections were found, and it can only be assumed that some of the complexity of the culture reports resulted from secondary or even post-mortem bacterial invaders.

The pathogenesis of the lesion has for years interested pathologists. The great variety of theories that have been offered in explanation of this infrequent type of kidney infection bears eloquent testimony to the fact that to date no adequate pathogenesis has been described.³

Although we have no new hypothesis to advance, certain features of the histologic picture seem to be more consistent with one of these hypotheses than with the others. Certainly, the infarct-like necrosis of the lesion suggests that ischemia of the pyramids is important in the development of the lesion. Moreover, papillary ischemia as the cause of this necrosis best explains the occurrence of the lesion in the apparently widely divergent group of diabetic patients with no urinary obstruction and in nondiabetic patients with urinary obstruction.

In both groups, capillary thromboses, marginal inflammation and masses of bacteria are demonstrable. But in the diabetic cases the greater amount of reaction, with the massive bacterial aggregates and marked cellular exudate, apparently compresses and collapses the thin-walled, capillary-like channels that traverse the pyramid between the tubules. In the nondiabetic group, whereas the inflammatory reaction is less marked and internal pressure is therefore less, the added factor of urinary obstruction and hydronephrotic pressure externally about the

pyramid and within the tubules seems to make up for this decrease in internal pressure within the papilla

It can thus be seen that the apparently widely differing clinical circumstances, such as diabetes and urinary-tract obstruction, actually produce essentially the same disturbance in the normal physiology of the kidney — reduction in papillary blood supply to the point of infarction

SUMMARY

Twenty-six autopsied cases of necrotizing papillitis of the renal pyramids are presented from both the clinical and pathological viewpoints, 19 of which occurred in diabetic and the remainder in non-diabetic patients. It is to be emphasized that this lesion is a frequent type of acute pyelonephritis in diabetic patients. It is seen far more rarely in non-diabetic patients and when present is associated with urinary-tract obstruction.

Clinically the cases divide themselves into a "fulminating" and a "subacute" group. In the former the presenting syndrome was one of the sudden onset of severe systemic infection, often without localizing signs. The "subacute" cases usually had obvious acute pyelonephritis for weeks to months until, without apparent prodromal symptoms, the urinary-tract infection became much severer and the course assumed the character of the "fulminating" cases.

Viewing both groups as a whole, most of the patients died of rapidly progressing uremia — 8 in the diabetic group and all 7 of the nondiabetic patients. Some of the former, however, showed little renal insufficiency and died of overwhelming infections.

In 74 per cent of the cases studied the death of the patient could be attributed primarily to this specific renal lesion.

Pathologically the lesion is readily recognized by the pale yellow-white, infarct-like necrosis of the papillae, bordered above by a green-to-red zone of inflammatory reaction.

The pathogenesis of this lesion is uncertain and appears to be unrelated to any specific bacteria. It probably represents a severe type of inflammatory renal disease to which the diabetic patient and the patient with urinary-tract obstruction are peculiarly susceptible.

Ante-mortem clinical diagnosis of this lesion, which is rarely made, is frequently possible only if the lesion is considered and if, in the presence of obvious urinary-tract infection, a rapidly rising non-protein nitrogen and anuria are encountered, especially in diabetic patients. In the later stages characteristic pyelographic changes are often demonstrated.

ANOXIA NEONATORUM*

CHARLES LEAVITT SULLIVAN, M D †

BROOKLINE, MASSACHUSETTS

OLIVER Wendell Holmes, lecturing in anatomy to the students at Harvard Medical School, held aloft the skeleton of a female pelvis and delineating the pubic arch, said, "This, gentlemen, is the triumphant arch, beneath which all heroes must pass as the first hazard to be overcome along the path to their ultimate coronation." Dr Holmes apparently gave little consideration to birth by cesarean section, but today it is known that that particular method of entrance into this world is not without its inherent perils to incipient heroes. I doubt whether Holmes was cognizant of the problems of anoxia, but then, as now, babies were born destroyed, as in death, and born mutilated, by partial irreparable damage, owing to oxygen lack during the accomplishment of their birth, he recognized this fact in his romantic description of that particular portion of the female pelvis.

In the present state of incomplete knowledge of the inaccessible and parasitical fetus, the distinction between the physiologic and the pathologic is indeed narrow. As a basic fact, it is known that adequate oxygenation of the tissues must be maintained if life is to remain in the body and that, whatever the inciting cause of a lethal syndrome, it is ultimately lack of oxygen availability or utilization that kills or maims. This is the one common denominator in all fetal deaths and permanent injuries. Anoxia, it is extremely important to realize, results not only from failure of respiration at birth, although this, of course, is the most frequent cause, but also from a series of pathologic events that may start at the time of nidation of the fertilized egg, with the formation of an inadequate placenta, or that may occur at any time during the prenatal, transnatal or postnatal period.

Clifford,¹ in a careful and well documented account of anoxemia, substantiated by complete obstetric, pediatric and autopsy records, has demonstrated the general pathologic effects involving the whole organism as a result of oxygen lack, even though symptoms referable to one part of the body, such as pulmonary atelectasis and intracranial injury, dominate the picture. The essential pathologic changes due to anoxia are summarized as congestion, edema, hemorrhage and, finally, tissue degeneration. The actual symptoms encountered, as well as their severity, depend on the degree and duration of anoxia and on the susceptibility of individual tissues affected. At one end of the scale,

these changes lead to death and from this point on there is a gradation of effect, through the symptomatology due to outright destruction of nerve tissue up to impairment of intelligence. This point was well demonstrated by Darke,² who in a study of the intelligence quotients of children who had suffered from acute oxygen lack at birth in comparison with those of their parents and siblings, showed that as a rule such children were retarded in later life. Preston,³ in a similar investigation, demonstrated arrest and interference with physical, nervous, mental, emotional and personality development from the same cause.

The responsibility for stillbirth and natal and neonatal mortality and morbidity is a joint one of the obstetrician and the pediatrician, nursing care providing the most important aspect of either effort. The pediatricians are to be complimented for their excellent progress with their end of the bargain. The main difficulty confronting the obstetrician is the completely normal course of most of his cases, which in turn causes an individual complacency and thus deprives the fetus or neonatal infant of the care and attention that might otherwise assure its constitutional adequacy at the time of birth. The percentage of poor results in the delivery of 50 to 100 cases a year does not give the obstetrician a full realization of the similar tragedies involved in 86,000 deliveries, such as those in Massachusetts in 1943. Anoxia is not a matter of percentage or statistics but rather of care and attention that result only from comprehension of the problem. The first question that one may justifiably ask is how these facts may be applied to clinical obstetrics and what can be done about them. The answer is that the obstetrician's own ingenuity is the limiting factor in listing the cause and effect productive of anoxia. The old adage "an ounce of prevention is worth a pound of cure" is nowhere better illustrated than in the prenatal and transnatal period.

The following discussion is limited to the care of the fetus during labor and to the evaluation and treatment of anoxia caused by failure of respiration after birth.

* * *

In any consideration of the care of the fetus during labor, it is essential to remember that, in general, conservative methods are more valuable than the radical ones and that any procedure that benefits the mother is also best for the fetus. The length of labor is of primary importance, anoxia is most frequent in labors under three and those over

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 21, 1946.

†Assistant obstetrician, Massachusetts General and Saint Elizabeth's hospitals.

thirty hours. If a labor extends over thirty hours, it is best terminated spontaneously, in the interest of the fetus, without operative interference. The average full-term fetus withstands without severe anoxia a labor lasting twenty to twenty-four hours, including contractions of forty seconds' duration at intervals of from two to five minutes, the parturient mother meanwhile being supported by fluids, glucose, vitamins and oxygen.

My gratitude and my sympathy go to the nurses who attend the medicated patients throughout labor — along with the boredom they have a great responsibility, not only to the fetus but also to the doctor who entrusts it to their care. The fetal heart should be checked every fifteen minutes during active labor of the first stage, and after every other contraction at the end of this stage and during the second stage. It is only through this extra effort on the part of the nurse that the four or five cases in a hundred that would otherwise be lost have an opportunity for salvage. Fetal heart rates of 116 to 160 are in the accepted range of normal. Any deviation from these arbitrary figures should receive immediate treatment by the administration of pure oxygen to the mother, the nurse is the only one in a position to do this in the emergency that may occur at any time during labor. The oxygen is transported directly to the fetus, and its results — in the restoration of a strong fetal heart at a physiologic rate — are as startling as they are reassuring in the vast majority of cases.

The crowning blow to the fetus, battered by hours of labor, is the administration of anesthesia at the time of birth, which results, in many cases, in serious anoxia. For spontaneous or outlet forceps delivery, especially in the face of previous medication, the amount of anesthesia used to complete labor should be absolutely minimal, being sufficient only to dull the pain sense of the mother, or, to use a phrase, sufficient only "to keep her in the room." Nitrous oxide and oxygen should be used in concentrations of 50 per cent each, with a few short inhalations of ether when this is not sufficient. With the head crowning, pure oxygen should be administered to the mother and continued after birth until pulsation of the cord ceases. In operative deliveries — that is, any delivery more serious than outlet forceps — spinal anesthesia is best from the standpoint of anoxia neonatorum (obstructively, version and extraction contraindicate its use because of the continuance of uterine contractions under spinal anesthesia). With spinal anesthesia the mother and infant receive the benefits of pure oxygen inhalation during the entire operative procedure. This advice is given not without a word of caution: the spinal anesthetic should be administered by a competent anesthetist, qualified to treat all its complications, which are more frequent in the pregnant woman, and in a dosage sufficient to

give only relaxation of the perineal soft parts, a so-called "saddle anesthesia."

The greatest single factor contributing to anoxia neonatorum and complicating approximately half the 4 to 5 per cent of neonatal deaths is failure of the onset of respiration after birth. It is essential to have a standard of normal so that deviations from the accepted physiologic response of the respiratory system at birth can be immediately recognized and treated. Respirations should be established within thirty seconds of birth and accompanied by a vigorous cry. The newborn infant should have muscle tone — its absence indicates a dangerous state of anoxia requiring immediate treatment. In the normal infant the time spent in suspending the baby head down and milking the trachea upward toward the mouth to express mucus and debris, as well as the tactile stimulus of brisk rubbing of both sides of the thoracic cage, should initiate the onset of normal respiration. Failure at this point indicates an underlying anoxia, and its severity is best judged by the classification of Flagg,⁴ who determines three stages — depression, spasticity and flaccidity, occurring in that order of frequency and severity.

In the first stage, namely, that of depression, the infant does not breathe well and there is a tendency to dusky skin and recurring cyanosis. Muscular tone is good, and the cord pulsates strongly. Respirations may be free but are slow and irregular. In the treatment of this stage, the infant should be placed in a slightly inclined position with the head downward to promote postural drainage and the mouth and pharynx cleared of mucus and debris by suction, with either a rubber ear syringe or a soft catheter. Body heat should be maintained, preferably by a warm, sterile blanket. Pure oxygen should be administered until the skin shows a pink glow, indicating sufficient oxygenation. If after this stage is reached the baby does not become vigorous, with deep respirations and a cry, it is worth while to stimulate it further with carbon dioxide, and this may readily be done by mouth to mouth insufflation. This will give the infant 5 per cent carbon dioxide, which is regarded by physiologists as a stimulus to the respiratory center. A most important point to remember in the administration of gases to the newborn, is that the lower jaw must not be depressed, for to do so produces an artificial respiratory obstruction. The proper position for the head is slight hyperextension, cradled in the fingers of the hand of the operator and with the thumb forcibly supporting the lower jaw upward. In most cases the procedures mentioned above will ensure the onset of adequate oxygenation and efficient respiration.

The second stage is one of spasticity and is more serious in degree. Respirations, which are irregular, gasping or shallow, occur at long intervals. Reflex

action, such as movement of the facial muscles and extremities in response to suction of the pharynx, is still present. Muscle tone is present but diminished in degree. There is marked cyanosis of the mucous membranes, with blotching of the skin or generalized pallor. Froth or fluid is present in the mouth. The circulatory system is intact, as indicated by the pulsating cord. In the treatment of this stage, the general measures described above are carried out—that is, maintenance of heat, proper position and suction of the upper air passages. It is essential to maintain body heat, and in the absence of warm blankets, the infant should be immersed in a tub of warm water to the neck line. Oxygen should be administered, preferably by a positive-and-negative-pressure machine, which should be regulated to thirty or forty discharges a minute. The machine should be used until the skin becomes pink and the respirations regular—if the machine is employed further at this point the infant's physiologic efforts to set up a respiratory rhythm of its own will be interfered with, a shift should be made to a straight flow of oxygen without alternating positive and negative pressures. In the event that the baby remains pink but does not increase its depth of respiration or cry, 5 per cent carbon dioxide should be resorted to for its stimulating effect. In the absence of a resuscitator, mouth-to-mouth breathing should be initiated at once and maintained until spontaneous respiration is established. In mouth-to-mouth insufflation the proper technic is to cover the nostrils of the infant and to fit the operator's mouth over that of the infant, with a few layers of gauze separating the two. The mouth is filled with air, and the glottis is closed, pressure is applied only by the operator's cheeks. For further protection against rupturing the alveoli during this procedure, the operator's hand should be placed over the thoracic cage of the infant, and there should be only a minimal excursion of the chest wall with each breath blown. Failure to observe these precautions may result in serious damage to the alveoli of the infant's lungs. The mortality and morbidity in this stage are about four times those in simple depression.

The third stage is one of flaccidity and indicates a most precarious state of shock, with circulatory failure, which occurs in about 15 per cent of all such cases and accounts for 75 per cent of all such deaths. Respirations at this stage occur at long intervals or cannot be demonstrated. Pallor or a gray cyanosis is present, and there is a complete

lack of all muscle tone. The apex beat may or may not be demonstrable, and there is no pulsation in the umbilical cord. In these infants, owing to complete lack of tone, there is respiratory obstruction from juxtaposition of the tongue, soft palate and pharynx. In treatment, which should be instituted at once, the general measures discussed above should be carried out, with the important addition of intubation, at first with suction and then with insufflation of gases as outlined in the discussion of the previous stages. Intubation may be indirect, with a catheter, or direct, by use of a laryngoscope, depending on the experience of the operator and the equipment available. The latter is preferable but both methods are adequate. Without intubation, it is impossible to give the infant an adequate supply of oxygen before irreparable damage has occurred to the nervous system.

The administration of drugs to stimulate the respiratory system in these cases is at best debatable, that their use is not without danger is indicated by the fact that in the presence of anoxia they have no effect but that soon after anoxia is relieved by other measures, the stored stimulus may be so powerful as to cause convulsions, with resultant further cerebral damage.

* * *

It is vital to remember that the newborn baby who does not breathe normally is either in or close to a condition of shock and that the utmost gentleness is mandatory, along with the conservation of body heat. The airways must be cleared immediately and completely. It is best to start with pure oxygen to combat anoxia and shock and when this is accomplished, if a satisfactory respiratory response has not been made, to shift to 5 per cent carbon dioxide in an attempt to stimulate the respiratory center. All infants requiring treatment for anoxia should be given the same meticulous care and attention accorded premature infants and should be placed in an incubator at a temperature of approximately 90°F with continuous oxygen for six to twelve hours, being at all times under careful observation.

DEATH FOLLOWING EXPOSURE TO DDT

Report of a Case

WILLIAM R. HILL, M.D.,* AND C. ROBERT DAMIANI, M.D.†

BOSTON

Numerous authors¹⁻³ have described the toxic effects observed in different species of warm-blooded animals exposed to DDT—2,2 bis (p-chlorophenyl)-1,1,1-trichloroethane—in various ways. By and large, clinical⁴ and pathological⁵ studies of these animals revealed that the principal action of DDT was on the central nervous system and liver.

The general consensus is that, used with reasonable care, preparations containing DDT do not present significant toxic hazards to human beings. Case,⁶ however, reported toxic effects of a 2 per cent solution of DDT on 2 men exposed for forty-eight hours under special conditions, consisting of an oily surface, large areas of skin exposed, high temperature and relative humidity. These effects included an increased destruction of erythrocytes, a decrease in the mean corpuscular content of hemoglobin, an increase in reticulocytes, a diminution of polymorphonuclear leukocytes accompanied by the appearance of immature white cells and the appearance of indoxyl sulfate in the urine. The symptoms and signs included tiredness, heaviness and aching in the limbs, diminution of some reflexes, unilateral slight impairment of hearing, transient yellow vision (in 1 subject), muscular fibrillation (in 1 subject), peripheral patchy anesthesia (in 1 subject), weakness of the legs and a curious apprehensive state. A return to normal took between twenty-six and thirty-three days.

Wigglesworth⁷ mentioned the case of a laboratory worker who allowed small quantities of an acetone solution of DDT to evaporate on the back of his hand. In the course of these experiments, a solution of acetone containing 25 gm of DDT was added to an inert dust and the mixture was kneaded with the hands for some minutes. Three weeks later, the patient was forced to go to bed because of continuous aching in the limbs, sleeplessness and acute anxiety. Involuntary muscle tremors also developed. Recovery was gradual and was not complete at the end of a year.

Hill and Robinson⁸ reported fatal poisoning in a child who drank an ounce of liquid from a bottle containing 5 per cent DDT in kerosene, the dose was approximately 150 mg per kilogram of body weight of commercially pure DDT. Within ten minutes, the child began to cough and vomit. An hour and a half later, convulsions and coma ap-

peared. Death took place four hours after the solution had been drunk. Autopsy showed minimal and indefinite changes in the lungs, liver and spleen.

The purpose of this paper is to report an additional fatal case following exposure to DDT, together with the findings at autopsy.

CASE REPORT

C. C., a 47-year-old, automobile electrician, was admitted to the Massachusetts General Hospital on December 12, 1945, with the complaint of weakness, loss of weight, dermatitis and asthma. Prior to this illness, he had enjoyed good health. No history could be obtained of eczema, asthma, hay fever or migraine in either the patient or his family. On November 10, he had been exposed while at work to a 6 per cent solution of DDT in kerosene. A few hours before he reported to work on that day, the room where he worked with eight other men, measuring approximately 36 x 20 x 10 feet, had been sprayed with the solution. Later in the same day, the patient had resprayed his corner of the room with the contents of the same bottle.† He was conscious of having inhaled the fumes and of contact of his perspiring skin with the solution. He had noted no untoward symptoms until the following morning, when an extensive pruritic eruption had appeared on the trunk and extremities, but had spared the skin of the face. He had also complained at that time of dyspnea and an unproductive cough. During the 5 weeks prior to admission, the cough and dyspnea had become severer. The eruption, which had regressed a few days after the onset, reappeared 1 week later. The patient had remained ambulatory until several weeks before admission, when he had gone to bed because of increasing weakness and a loss of 20 pounds.

During the interval prior to admission, the only medication administered by the patient's attending physician was adrenalin in a strength of 1:1000 given subcutaneously on several occasions. On December 12, one of us (W. R. H.) was consulted and advised hospitalization.

Physical examination revealed an acutely ill and dyspneic man, with a paroxysmal, unproductive cough. The mental status was one of agitation and apprehension. Over the entire cutaneous surface, with the exception of the face, there were numerous discrete, reddish-purple maculopapules varying in size from 2 to 8 mm. Many of these lesions presented an excoriated surface. On one lower extremity, the lesions were hemorrhagic. An ecchymotic area, the size of a twenty-five-cent piece, was noted on the glans penis. The pharynx was dusky red. The tongue was covered with a dry, brownish membrane, and the lips had hemorrhagic crusts. The thorax was emphysematous and hyper-resonant to percussion, with coarse respiratory rales throughout both pulmonary fields. Loud, musical rhonchi were also heard. To percussion, the heart was normal in size. The sounds were of good quality. There were no murmurs. A blood pressure of 110/70 was obtained. The temperature was 98°F, the pulse 120, and the respirations 30. The abdomen was moderately distended, but there was no tenderness or spasm. The liver and spleen could not be palpated. Small, nontender, pea-sized, anterior cervical and inguinal lymph nodes were palpable bilaterally. There were no discernible neurologic signs. A presumptive diagnosis of periarteritis nodosa was made.

Laboratory examination of voided urine revealed an acid reaction, a trace of albumin and no sugar, on microscopic

†Resident in dermatology, Massachusetts General Hospital.

‡According to Dr. Hervey B. Elkins, chemist in the Division of Occupational Hygiene, Massachusetts Department of Labor and Industries, 130 cc of 6 per cent DDT had been sprayed on these two occasions into a room with a capacity of roughly 8000 cubic feet. If the spray had been uniformly distributed and none had adhered to the walls, a concentration of 20 to 30 mg of DDT per cubic meter of air would have resulted.

examination there were 15 erythrocytes, 5 leukocytes and rare granular casts per high-power field. Examination of the blood showed a hemoglobin of 12.2 gm (photoelectric-cell technic) and a white-cell count of 43,000, with 72 per cent neutrophils, 1 per cent lymphocytes, 2 per cent monocytes, 20 per cent eosinophils and 5 per cent blast cells, the erythrocytes showed moderate achromia, and the platelets were normal. The sedimentation rate was normal—8 mm in 60 minutes (Westgren). Roentgenographic examination of the thorax showed prominence of the lung roots, with enlargement of the hilar lymph nodes, and going out into each pulmonary field from the enlarged nodes were ragged, linear regions of increased density that extended to the periphery. These findings were reported as consistent with periarthritis nodosa. Chemical studies of the blood, including the serum protein, nonprotein nitrogen, serum phosphorus, alkaline phosphate and carbon dioxide combining power gave normal results. An electrocardiogram was normal except for sinus tachycardia. Repeated blood cultures showed no growth.

A week before death, examination of the urine for organic chlorides, which are said to be increased following DDT ingestion,⁴ was performed, with negative results. (In this case too much time had probably elapsed for the test to be of value.)

On the 2nd hospital day, after the temperature had risen to 103.5°F, 40,000 units of penicillin were administered every 3 hours, night and day. This was continued throughout the hospital stay but had no influence on the temperature, which fluctuated between 102 and 104°F, or on the course of the illness.

On the following day, because of increasing respiratory distress, the patient was placed in an oxygen tent. A few hours afterward, he complained of numbness of the left side of the face and of the index and middle fingers of the left hand. Examination revealed no motor or sensory dysfunction at these sites. The involved fingers were quite cyanotic. The paresthesia disappeared from the face in 12 hours but persisted in the fingers for several days.

On December 15 the edge of the liver was palpated three fingerbreadths beneath the costal margin and was sharp but not tender to palpation. A cephalin-flocculation test was reported to be + + + +. The white-cell count was 40,000, with 61 per cent neutrophils, 10 per cent lymphocytes, 4 per cent monocytes and 25 per cent eosinophils.

On December 18 the patient became slightly confused, and fine tremors of the hands and face developed during movement. The pupils were irregular but reacted fairly well to light and accommodation. Ophthalmoscopic examination showed blurring of the disk margins, as well as distention and tortuosity of the retinal veins. A lumbar puncture, performed 3 days later, showed an initial pressure equivalent to 350 mm of water, the fluid was colorless, and the total protein normal. On December 28 the red-cell count was 3,070,000, with a hemoglobin of 9.5 gm. Specimens removed for biopsy from cutaneous lesions of the left arm and leg, as well as from the muscle of the left lower leg, were reported as showing periarthritis nodosa of both the skin and muscle.

The patient's condition continued to become progressively worse. He became weaker, emaciated and drowsy. The chief complaint at that time was dysphagia. Superficial erosions, covered with a grayish exudate, appeared on the lateral and posterior pharyngeal walls. Because of inability to take nourishment by mouth, the patient was given 1500 cc of saline intravenously each day, together with 1500 cc of 10 per cent glucose mixed with 500 cc of 10 per cent Amigen, 2 cc of Betalin Compound and 100 mg of Cevalin. Transfusions with 500 cc of whole blood were given on January 2 and January 4. On January 6, the temperature rose to 105°F, the pulse to 145, and the respirations to 35. The breathing became more labored, and moist rales were heard throughout both pulmonary fields. The patient failed to respond to therapy and expired at 6:30 a.m.

Autopsy. At post-mortem examination, performed 4½ hours after death, there were purplish petechiae scattered over the serosa and mucosa of the small bowel down to the midportion of the ileum. Peyer's patches and lymphoid follicles were prominent and purplish gray. In the large bowel, there were also a few scattered petechiae. The combined weight of the lungs was 2350 gm. The pulmonary tissue was heavy, boggy and somewhat nodular and firm, particularly in the lower portion of the right upper lobe. The

parenchyma was reddish, with scattered firm, gray and dark-red granular regions measuring up to 2 cm in diameter. The left lung was similar to the right and had regions of gray consolidation scattered throughout. The cavities of the heart were of normal size, and the valves were normal. The liver weighed 2080 gm. The capsule was smooth and transmitted the reddish-brown color of the parenchyma. On section, lobulation was prominent, with large, purplish central regions. The hepatic artery and vein were normal. The kidneys weighed 200 gm each. The capsule stripped readily and revealed a smooth, pale, purplish surface with scattered dark blotches measuring up to 2 cm in diameter. On section, there were dark-purple regions extending radially into the cortex. Elsewhere, the parenchyma was grayish purple and showed regular striations. The glomeruli were pale and bloodless. There were a few dark-red petechiae in the mucosa. The renal vessels were normal. The brain was grossly normal. The right ethmoid and sphenoid sinuses contained a moderate amount of thick, yellowish, purulent material. The upper cervical segment of the spinal cord was not remarkable. The sciatic nerves and the brachial plexus were grossly normal. The brain section after fixation was normal.

Microscopic examination of the lungs showed diffuse bronchopneumonia, with a tendency toward abscess formation in areas of both lungs. The exudate was mainly fibrinopurulent, but erythrocytes and macrophages were frequent. The bronchioles were heavily infiltrated by mononuclear cells and lymphocytes, and some of the thickened walls appeared to consist almost entirely of loose granulation tissue indicating a chronic inflammatory process. The epithelial lining showed various stages of desquamation, and purulent exudate was found in the lumens. Surrounding the bronchioles the pneumonic process was somewhat older than elsewhere, with cuboidal metaplasia of the epithelium in some alveoli and occasional plugs of fibrin infiltrated by large mononuclear cells.

The splenic tissue showed a pathologic process that had been active for a period of weeks or months. The most definite changes were in the corpuscles, which showed a considerable increase in collagen and a decrease in lymphocytes. Plasma and mononuclear cells were abundant, some appearing immature with deeply basophilic cytoplasm. Granules of hemosiderin were frequent both outside and within phagocytes. The red pulp also had a dearth of lymphocytes and appeared congested. Some of the trabeculae were infiltrated by lymphocytes and mononuclear cells. In one section, there was a small infarct with an outer zone of organization and a necrotic center. One of the arterioles contained a fibrin thrombus beginning to undergo fibroblastic invasion.

The central regions of the liver were congested, and there was a moderate fatty change in the periportal regions. One of the large veins contained a fibrin thrombus that bulged out into the lumen and was already covered by endothelium and invaded by fibroblasts.

Some cortical cells of the adrenal glands were necrotic and scattered rounded spaces in the fasciculate cords appeared as if entire cells had dropped out of place.

In the kidneys there were scattered infarct-like regions of parenchymal atrophy and regeneration. The changes were most marked in the tubules, which were small and appeared compressed by the increased amount of vascular connective-tissue stroma. Most of the tubular epithelium was hyperchromatic, as if recently regenerated, but in places the cells were pale and granular, with pyknotic and fragmented nuclei. There were also a moderate number of hyaline casts and a small amount of interstitial infiltration by lymphocytes, mononuclear cells and occasional polymorphonuclear leukocytes. One of the large veins near the hilus contained a thrombus in the process of early organization.

Unquestionably, many persons exposed to DDT will subsequently experience the development of an undiagnosable disease, which will be incorrectly accredited to DDT. In spite of the fact that Neal and Von Oettingen⁹ stated that there is no definite evidence that DDT exerts a sensitizing effect on the skin or produces other allergic reactions, such as asthma, and although, in the case reported above, the exact cause of death could not be determined

at autopsy, it is believed that true allergy to DDT was exhibited and that death was attributable to sensitization by this drug. It is also fair to state that the authors referred to did not observe toxic symptoms in any animals that were exposed to an atmosphere containing many times the recommended insecticidal concentration of DDT when used as an aerosol, mist or spray.⁹

It seems to be more than coincidence for a man who, so far as could be determined, had enjoyed previous good health to experience symptoms twenty-four hours after his first exposure to DDT, and to show subsequently a classic clinical picture supported by laboratory evidence, including blood, urine, biopsy and roentgenographic findings, of periarteritis nodosa. Rich¹⁰⁻¹² and Rich and Gregory¹³ showed that a similar clinical and laboratory picture occurred in persons who had been exposed to sensitizing drugs, such as iodides and sulfonamides, and have claimed that periarteritis nodosa is a hypersensitive state induced by these drugs. It is reasonable, therefore, to assume that DDT also possesses these allergenic properties and should be included among the drugs capable of producing a sensitizing reaction manifested clinically by a picture simulating that of periarteritis nodosa.

The fact that the patient exhibited tremors, a confused mental state, paresthesia and severe loss of weight, symptoms reported both in animals and in human beings as being directly related to DDT intoxication, strengthens the relation of DDT to the final illness.

Even though this is an isolated case, we consider ourselves justified in calling the attention of the medical profession to it, in the hope that it will encourage others to be on the lookout for similar reactions, which, if they occur, will lend support to our assumption.

SUMMARY

A case in which death occurred twenty-five days following exposure to DDT—2,2 bis(p-chlorophenyl)-1,1,1-trichloroethane—is reported. The symptoms, which began in a previously healthy man within twenty-four hours after exposure, were similar to those already reported as due to DDT intoxication. The disease picture, both clinically and at biopsy, simulated that of periarteritis nodosa, and it is assumed that DDT possesses allergenic properties and should be included among other drugs that are believed to be capable of producing such a sensitizing reaction.

MEDICAL PROGRESS

DIAGNOSIS AND TREATMENT OF SKIN MANIFESTATIONS OF CAPILLARY FRAGILITY*

SAMUEL M. PECK, M.D.,† AND ALFRED L. COPLEY, M.D.‡

NEW YORK CITY

THIS subject is discussed under the following headings: vascular anatomy of the skin, with special reference to the site of capillary reactions, the methods of testing capillary fragility, the mechanisms of capillary fragility, the clinical manifestations of capillary fragility as part of general diseases and as purely dermatologic conditions, the relation of capillary-fragility tests to clinical diagnosis, and treatment.

VASCULAR ANATOMY OF THE SKIN, WITH SPECIAL REFERENCE TO THE SITE OF CAPILLARY REACTIONS

The skin is supplied from the underlying tissues through small arteries. In the deepest portion of the cutis the arteries form a rich anastomosing plexus from which small arteries rise perpendicularly to form a subpapillary plexus from which smaller vessels supply the papillary capillaries. These do not anastomose, but each supplies a small but variable number of papillae. Each papilla is normally furnished by a central capillary loop, whose arterial branch is narrow and widens toward the tip to the subsequent venous branch, which may be 0.02 mm or more in diameter. The venous branches of the papillary capillaries then continue to form venules, which return first to a subpapillary plexus of veins. These are connected by short anastomoses with a second venous plexus, which lies at the arterial subpapillary vessels. Between the cutis and the subcutis, valves appear in the veins. No valves are seen in the venules of the cutis.

There is no sharp distinction between the smallest capillary arteries,¹ the capillaries proper and the venules (capillary veins). Lewis² introduces the term "minute vessels" of the skin to distinguish the aforementioned vessels from the "strong arterioles" and the "deep veins."³

Chambers and Zweifach⁴ recently studied the topography and function of the capillary circulation on the mesentery of the rat and dog. The fundamental architecture and physiologic activity of the capillary bed in the mesoappendix of the rat and

in the omentum of the dog were found to be identical in both tissues. No such studies have been made in the capillary bed in human skin. According to these authors, a precise mechanism exists for controlling the rate and the amount of blood flow through the capillary bed. In conclusion, they present the following description:

Muscular elements are present in the capillary bed proper but, instead of being indiscriminately distributed, as indicated by Krogh and his supporters, they are restricted to the well-defined, capillary-like, central channels and their precapillary offshoots. The channels serve as thoroughfares from arteriole to venule and, in this sense, may be regarded as similar to the arteriovenous anastomoses. Functionally, however, they serve a different purpose. They are relatively long vessels and bear a close relationship to the true capillaries. Under normal conditions the central channels always remain open so that any spontaneous restriction of flow is caused by contraction of the precapillary offshoots only.

The recurrent vasomotion of the metarterioles is the factor which controls the rate of flow through the central channels, while the alternate opening and closing of the sphincters of their precapillary offshoots induce an intermittent flow through the true capillaries without interfering with the flow in the central channels. Even during the intervals when their supply of blood is shut off, the capillaries generally contain a fluid. This fluid doubtless diffusing in from the interstitial spaces, is carried by way of the post-capillaries into the distal segments of the central channels and the venules.

A significant feature of the muscular components of the capillary bed, particularly the metarterioles and precapillaries, is their reactivity to epinephrine and to nerve stimuli and their susceptibility to local changes in the condition of the tissue in which they lie. When the tissue is in a state of comparative rest the periodic phases of vasomotion are augmented. This results in a restriction of the circulation to the central channels except for a sporadic blood flow in the true capillaries. Resting tissue is thus relatively ischemic. When the tissue is activated, as by mechanical irritation, so that conditions arising from the tissue predominate, the vasomotion ceases and the metarterioles and precapillary sphincters become dilated. Thereupon, the capillaries become flooded with blood and hyperemia results. The metarterioles and precapillaries form an integral part of the capillary bed proper and their reactive muscular elements are so disposed as to be fully exposed to chemical changes in the environment.

Chambers and Zweifach believe that in the visceral tissues there is the functional autonomy of the peripheral vascular system. An evaluation of the reactions of the capillary circulation has been made possible by their finding that the capillary bed possesses a peculiar architecture with a highly specific responsiveness of its muscular vessels. The most reactive structures are the metarterioles, with their dispersed muscle cells, and the sphincters of the precapillaries. These readily undergo constrict-

*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 23, 1946.

tion through nervous impulses and, conversely, undergo dilation by a-refractoriness to nerve impulses when metabolic waste products accumulate about them. Thus, local tissue conditions can affect the responsiveness of the vasomotion, counteracting the effectiveness of the vasoconstriction.⁵ It will be of interest to learn whether, or to what degree, the findings of Chambers and Zweifach coincide with the vascular anatomy and function of the human skin.

METHODS OF TESTING CAPILLARY FRAGILITY

No exact method is available for the evaluation of capillary resistance. Thus far, methods have been too general and subject to too many variables. Two methods of approach were followed mainly during the last twenty-five years to determine capillary strength. Both depended on the production of skin hemorrhages presumably due to rupture of capillary walls. The suction or negative-pressure test introduced by Hecht⁶ measures the amount of partial vacuum that must be applied to the skin to produce petechial hemorrhage. The original apparatus of Hecht has been modified by a number of workers. Da Silva-Mello⁷ constructed the so-called "capillary resistometer." A similar device was developed by von Borbély⁸ and applied in studies on vitamin P by Szent-Györgyi and his associates.⁹ The other procedure is based on the Rumpel-Leede test, which depends on a quantitative approach by modifications of several authors. It consists in increasing the intracapillary pressure to the point where petechiae appear in the skin. This method was introduced in this country by Hess and Fish¹⁰ and named the "capillary-resistance test." Stephan¹¹ introduced the term "endothelial symptom" and claimed that a positive test signifies a pathologic condition of the endothelial cells of the whole capillary system. The procedure of Göthlin¹² measures the amount of pressure necessary to produce the petechiae. Direct microscopic observation of the affected vessel was introduced by Cutter and Marquardt.¹³ These authors observed the end of the nail bed. The finger of the subject was inserted into a glass holder attached to a negative-pressure apparatus. About half the cases showed the rupture point by petechiae, in the remainder it was assumed that a gap in the capillary line not previously noted meant that rupture had occurred. The authors were unable to produce capillary damage in 14 of about 200 cases.

Koch¹⁴ introduced the so-called "puncture test," in which the skin is lightly pricked with a fine needle. If, on the following day, fine bleeding points are visible at the sites of the puncture, it is claimed that the patient shows a bleeding tendency. This test was later applied by Hess,¹⁵ who punctured the skin by a hypodermic needle and observed whether a hemorrhage resulted. He also observed whether numerous subcutaneous injec-

tions of diphtheria antitoxin in a case of diphtheria resulted in hemorrhage but found not the slightest extravasation at the site of injection.

Leschke¹⁶ used the puncture test as a starting point for his bleeding test. He injected subcutaneously 1 or 2 cc of a 0.2 per cent sodium chloride solution. He claimed that this saline concentration produced a stronger irritation than physiologic saline solution. In a patient with a bleeding tendency he found a subcutaneous hematoma, this was a case of thrombocytopenic purpura.

A better controlled skin test is that introduced by Peck, Rosenthal and Erf,³ which employs snake venom. The venoms of various species of snakes differ in their content of toxic principles, such as hemorrhagins, blood coagulants, hemolysins and neurotoxins. A method for the demonstration of hemorrhagins in snake venom has been devised by Witebsky, Peck and Neter.¹⁷ The venom used is that of the moccasin (*Agkistrodon piscivorus*). The venom is titrated by observation of the effect on the vascular bed of the chick embryo. The optimum dilution of venom in 1 cc of physiologic saline solution is that which produces petechial hemorrhages in the four-day chick embryo in a three-hour period. This is considered to contain 10 hemorrhagin units. Thus, 0.1 cc of standardized venom contains 1 hemorrhagin unit.

The intradermal venom test consists in the intradermal injection of 0.1 to 0.2 cc (1 or 2 hemorrhagin units) of standardized moccasin venom, the reaction being determined within thirty minutes to an hour. A solution of 0.1 to 0.2 cc. of physiologic saline injected at the same time served as a control. The test is positive when a definite capillary rupture or ecchymosis appears at the injection site within an hour. The ecchymosis may be 1 cm or more in diameter. A delayed positive reaction is one that shows a diffuse ecchymosis in twelve to twenty-four hours. A negative test is one that demonstrates no hemorrhagic discoloration of the skin.

The venom reaction can be used to determine local capillary fragility. Areas can also be used that are inaccessible to the tourniquet test, such as the cheek, the mucous membranes and the center or periphery of skin lesions.

The test appears to give valuable information in thrombocytopenic purpura hemorrhagica, both in the classification of such cases and in the prognosis. It was positive in symptomatic purpura associated with benzol poisoning, aplastic anemia, leukemia, subacute endocarditis and so forth. Although the purpura in those cases was closely related to the platelets, the test did not necessarily serve as an indicator of the platelet count alone. The venom test gave varying reactions in different types of purpura not associated with a diminution of the platelets.¹⁷ The mechanism of this action is not yet understood.

MECHANISMS OF CAPILLARY FRAGILITY

Bleeding or hemorrhage originates if whole blood escapes from a blood vessel. This phenomenon occurs from a variety of causes, some of which are known, whereas others remain obscure. Extravasation of blood is always due to a separation in the continuity of the blood vessel, which can be brought about by three major processes: rupture of a blood vessel, corrosive or ulcerative perforation of a blood vessel, and diapedesis through the unruptured, nonperforated wall of a blood vessel.

The first group usually comprises hemorrhage from simple and obvious causes, such as open injury and blunt, contusive and tearing forces. Rupture following formation of aneurysm or local dilatation of the lumen with a thinning wall may be taken as a pathologic process in this group. One may speculate that hyaluronidase affects the permeability of blood capillaries, as originally emphasized by Meyer and Chaffee.¹⁸ These authors explain the occurrence of hyaluronic acid in skin as an indication for the identity of the spreading factor and hyaluronidase in the so-called "spreading or diffusion reaction."^{19, 20} On the hypothesis that the capillaries and minute vessels are surrounded by a tissue containing hyaluronic acid, capillary permeability may be due to hyaluronidase activity that liquefies the surrounding tissue, with the result that the walls of the minute vessels are no longer adequately supported. The intravascular pressure then dilates the vessels to such a degree as to rupture them. In preliminary unpublished experiments with a certain bacterial toxin by Chambers and Zweifach,²¹ this possibility was experimentally corroborated.

The histologic studies of both clinical and experimentally produced purpuric lesions by Peck, Rosenthal and Erf² suggested that the tissues surrounding the minute vessels, especially the elastic fibers, play an important role in hemorrhage from blood-vessel rupture. The chief basis for their conception was the histologic studies of skin biopsies from patients with Schönlein-Henoch's purpura at various stages of the disease. In the active stages a toxic effect on the vessel wall was evidenced by purpuric manifestations all over the body, and the venom test then was positive, although somewhat different in type in all areas of the skin. When recovery occurred, the venom tests became negative in all areas of the skin. During convalescence and for some time thereafter, when the patient had become ambulatory, purpuric manifestations often occurred only on the lower extremities. The venom test was still negative throughout, even on the lower extremities, suction tests were sometimes positive on the lower extremities in such patients. In the ambulatory cases, histologic examination of skin biopsies from the lower extremities apparently showed changes in the elastic tissue, especially

around many of the small vessels. The vessels themselves seemed normal. These findings were interpreted as demonstrating that although the capillary vessels themselves had returned to normal, the loss of the cushioning effect resulting from the damage to the elastic tissue immediately surrounding the vessels gave rise to purpuric manifestations when there was an increased intracapillary pressure, as in walking. The venom test was negative in such cases because the vessels themselves had apparently returned to normal. On the other hand, tests like the suction tests were positive because petechiae produced by such a method also resulted when the resistance of the supporting structures immediately around the vessels was nullified.

Hemorrhage from perforation of blood vessels includes those due to burns and corrosive agents, as well as those due to various pathologic processes, as in gastrointestinal ulcers, in cerebral hemorrhage and generally in arteriosclerosis caused by a patch of atheroma and its corrosive action. It should be emphasized, however, that cerebral hemorrhage is also caused by arterial thrombosis or embolism. Under such conditions, attempts to accelerate blood clotting may serve to aggravate the bleeding. In typhoid fever and subacute bacterial endocarditis, for example, clumps of bacteria or platelet thrombi containing bacteria may lodge as emboli in the capillaries and cause hemorrhage. In the present state of knowledge it does not seem possible to decide whether menstrual bleeding belongs to one of the groups discussed above or to the third group.

Hemorrhage through the unruptured wall of blood vessels comprises conditions in which many small hemorrhages, often of the size of a pinhead, or petechiae, occur. Ecchymoses are apparently based on the same phenomenon and signify larger extravasations. Chambers and Zweifach²¹ made the observation that the interendothelial cement provides considerable cover for the endothelial cells facing the capillary lumen. This cement substance, when removed, permits hemorrhage. Chambers and Zweifach²² believe that the intercellular cement is secreted by the endothelial cells. On this basis, increased capillary fragility leading to extravasation may be due to injury of the cement substance or to inability of the endothelial cells to secrete this substance continually.

In septicemia it has been assumed that bacterial toxins injure the capillary endothelium and produce petechial hemorrhages, mainly in the serous membranes. Hemorrhagic purpuras, particularly, represent characteristics by the formation of purple patches on the skin and mucous membranes that appear to be based on this type of hemorrhage. In telangiectasia or angiomas, multiple localized dilatations of the capillaries and venules, particularly of the skin and mucous membranes, are found. In these hereditary or acquired vascular anomalies, spontaneous bleeding, possibly due to hemorrhage

through either ruptured or unruptured walls of blood vessels, occurs, trauma, however, is frequently the cause of hemorrhage of both types. Thus, in these hemorrhagic disorders bleeding may be brought about by any of the three major processes discussed above.

The above classification of the initial causes of bleeding by the three major processes that separate the continuity of the blood vessel does not suffice, since the phenomenon of bleeding has as a counterpart the phenomenon of hemostasis, which is defined as arrest of hemorrhage.

It is obvious that, because of the difference in the mechanisms of capillary hemorrhage, a single therapeutic approach to secure hemostasis cannot counteract the manifestations of capillary fragility. These phenomena have never been adequately studied, partly because no proper methods have been devised for their study. At present such investigations are being made by Chambers and Copley.²³

CLINICAL MANIFESTATIONS OF CAPILLARY FRAGILITY

General Diseases

Wiemer²⁴ differentiates the following factors that influence capillary resistance: those directly damaging the endothelium, including poisons, such as opium, neoarsphenamine, carbon monoxide, trypaflavine and iodine, toxins, as in scarlet fever, polyarthritus, measles, diphtheria, smallpox and influenza, metabolic products, as in uremia and acetoneuria, and vitamin deficiencies, such as scurvy, and those indirectly affecting the endothelium or capillary tonus, comprising physiologic variations, such as those previous to menstruation and in endocrinal disturbances, endocrine diseases, such as exophthalmic goiter and *climacterium virile*, and diseases of the spleen and the reticuloendothelial system. In addition to the conditions listed by Wiemer, increased permeability of the wall of peripheral vessels has been found in tuberculosis. In tuberculous children with purpura an increased bleeding time and a decreased capillary resistance were observed in association with a normal platelet count, coagulation time and calcium content.²⁵

The pathogenesis of essential thrombocytopenic purpura is poorly understood.²⁶⁻²⁷ Rosenthal²⁷ considered weakness in maturation or fragmentation of megakaryocytes an important factor in the origin of the disease. He briefly reviewed the literature of the disease. He briefly reviewed the literature pertaining to splenic functions that are possibly important in inhibiting thrombocytopoiesis. A similar view was recently expressed by Dameshek and Miller,²⁸ who postulate a hormonal relation between the spleen and the bone marrow and who regard the disease as being due to a form of hypersplenism in which the megakaryocytes of the bone marrow are inhibited from normal platelet production and delivery.

Increased capillary fragility and increased bleeding time correspond to the hemorrhagic tendency. Several workers consider lesions of the vessel walls to be the primary defect in this disease,²⁹⁻³¹ although the actual morphologic evidence of the presence of such lesions is not decisive.

It should be considered that increased capillary fragility as measured with the venom test of Peck, Rosenthal and Erf,³² a negative-pressure or positive-pressure test or with the new technics developed in animals by Chambers and Copley,²³ may not necessarily indicate an increased hemorrhagic tendency. In certain chronic conditions such as arteriosclerosis, hyperthyroidism and diabetes, increased capillary fragility may be present without the clinical picture of a hemorrhagic diathesis.

Dermatologic Conditions

A state of capillary fragility is not infrequent in many dermatologic conditions. Changes in the small vessels are seen, for instance, in such abnormalities as purpura due to drugs, Majocchi's disease, angioma serpiginosum, Schamberg's disease, pigmented purpuric lichenoid dermatitis, Kaposi's disease, Osler's hereditary familial telangiectasia, orthostatic purpura and dermatitis hemostatica.

RELATION OF CAPILLARY-FRAGILITY TESTS TO CLINICAL DIAGNOSIS

Several major processes concerned with hemostasis, either singularly or in some combination, are summarized as follows: clotting of blood due either to fibrin formation and blood coagulation or to platelet agglutination, blood-vessel changes, physical properties of blood clots, and adhesiveness of blood clots or so-called "wound thrombi" to the vessel wall. This classification is fundamentally identical with that of hemorrhagic disorders. It differs from the generally accepted division of bleeding diseases, which only accepts two primary groups—in which the hemostatic defect is vascular, and in which the mechanism of blood coagulation is disturbed. This limited classification of causes of defective hemostasis or hemorrhagic disorder not only omits significant phenomena, such as the physical properties and adhesiveness of blood clots, but also recognizes only one mechanism of blood clotting—namely, blood coagulation. The generally accepted contention is no longer tenable because of a series of findings made by Copley and his associates.³³⁻³⁹

Copley and Houlihan³³ showed that the agglutination of platelets is not brought about by fibrin formation and that the two processes are governed by different mechanisms. Copley and Lalich³⁴ demonstrated that the firmness of the clot and its property of adhesion to the traumatized vessels are probably important in maintaining hemostasis; they expressed the belief that both the agglutination of platelets and the conversion of fibrinogen to fibrin

are responsible for the properties of the clot that seals the wounded vessels. In a subsequent study on the mechanism of hemostasis they³⁵ emphasized that the clot that forms in a wound is similar to or identical with a thrombus and therefore designated such a clot as a "wound thrombus." On the basis of recent studies on platelet agglutination by Copley and Houlihan^{33, 36} and on coagulation thrombosis in arteries and veins of dogs by Copley and Stefko,³⁷ a new concept of the phenomenon of thrombosis was advanced.³⁸ According to this view, either the agglutination of platelets or the formation of fibrin with simultaneous or subsequent blood coagulation, and not necessarily always a combination of both phenomena, forms wound thrombi to effect initial hemostasis.

Few tests were available for studying hemorrhagic disorders. Since some of these procedures were improved by a number of workers and a series of new technics were developed by Copley and his associates, a reclassification of hemorrhagic disorders becomes necessary. The following tests are recommended for clinical study of hemorrhagic conditions in men: blood-saline coagulation time (Copley and Houlihan³⁹), prothrombin time—the one-stage method (Quick⁴⁰) and the two-stage method (Warner et al⁴¹), antithrombin content (Astrup and Darling⁴²), platelet count on both venous (Copley and Robb⁴³⁻⁴⁵) and cutaneous blood (Ottenberg and Rosenthal⁴⁶), platelet agglutination tests—macroscopic (Copley and Houlihan³⁶) and microscopic (Houlihan and Copley⁴⁷), clot-firmness test (Lalich and Copley⁴⁸), thixotropy and dilatancy tests (Copley et al⁴⁹), syneresis or clot retraction (MacFarlane⁵⁰), extracorporeal clot volume (Lucia, Aggeler and Hamlin⁵¹), bleeding time (Copley and Lalich^{34, 52}), clot resistance (Copley and Lalich^{34, 52}), and capillary fragility, including the skin venom test of Peck, Rosenthal and Erf,^{32, 53} the positive-pressure test of Göthlin¹² and the negative-pressure test of Da Silva-Mello⁷ and Cutter and Marquardt.¹³

The first nine tests aid in measuring the hemostatic function of the blood. The physical properties of the blood coagulums are measured by the tests for clot firmness, thixotropy, syneresis and extracorporeal clot volume. The hemostatic function of the skin is measured by the determinations of bleeding time, clot resistance and capillary fragility. The majority of hemorrhagic disorders will have to be restudied with the newer methods. Only then will it be possible to arrive at a proper diagnosis. It is our opinion that such studies not only will advance knowledge on hemorrhagic disorders but also will lead to a more intelligent and adequate therapy. Hemostatic agents are frequently used promiscuously to arrest hemorrhage. Unfortunately, poorly controlled usage of various hemostatic agents is both valueless for a better understanding of hemorrhagic disorders and possibly dangerous to patients.

TREATMENT

Most authors have reported no therapeutic success following the administration of large doses of vitamin C in other than clinical and subclinical scurvy. In a recent publication, Goldman and Corrill⁵⁴ reviewed the therapeutic results obtained with vitamin P; they reported that clinical trials with crude hesperidin and hesperidin methyl chalcone in patients exhibiting obvious capillary fragility were of no value. Transient and at times striking decreases in the positive tests for capillary fragility, however, were occasionally noted after the intravenous use of hesperidin methyl chalcone.

It has been shown in certain cases of thrombocytopenic purpura by Peck, Rosenthal and Erf,⁵⁵ and others^{27, 56} that therapy with moccasin venom was of some value. In a recent review of the classification and treatment of purpuric conditions Rosenthal⁵⁷ stated that nonoperative treatment of thrombocytopenic purpura was apt to be unsatisfactory if cases occurring in children and some acute cases in adults were excluded. Recovery was spontaneous in many idiopathic or infectious cases, especially in those due to drug idiosyncrasy. X-ray irradiation of the spleen, ascorbic acid given intravenously and orally and citrin were unsuccessful in the treatment of chronic purpura. There was no evidence of the value of sesame oil, liver extract or parathyroid extract in the treatment of idiopathic purpura. Blood transfusions were indicated in the presence of severe symptoms, to tide patients over the critical period until splenectomy could be performed. Snake venom, which was of value in the treatment of the nonthrombocytopenic forms of bleeding, hastened recovery in certain cases but was ineffective in acute thrombocytopenic purpura or in the acute forms in which there was a megakaryophthisis. In this group, severe reactions may follow the intracutaneous or subcutaneous injections of snake venom. In chronic cases in which the patients refused to submit to splenectomy, snake venom had some therapeutic value.

Rosenthal⁵⁷ reported on additional patients with chronic purpura treated with venom since the last published report with Peck. Only about 50 per cent of his cases showed symptomatic improvement following its use. His conclusions were as follows:

In no instance have we found a change in the number of blood platelets following the venom injections. In only a few has there been a tendency towards diminution in the bleeding time, but more frequently we have seen improvement in the condition of the capillaries as noted with capillary resistance tests. On the whole we believe snake venom therapy should be regarded only as a palliative form of treatment in this condition. The intracutaneous venom test, however, is of value from the prognostic standpoint, especially in the selection of cases requiring splenectomy. It has been noted that a reversal from a positive to the negative intracutaneous venom test, after repeated inoculations usually was associated with improvement. The persistence of positive intracutaneous tests usually indicates the ineffectiveness of venom treatment, and in a small number of cases, also failure to react to splenectomy.

Splenectomy is undoubtedly the most promising form of treatment and, in the great majority of cases, perhaps the only curative one, according to Rosenthal. He emphasizes the fact, however, that it is essential to weed out acute and apparently chronic cases in which splenectomy is contraindicated, and observes that the intracutaneous venom reaction and sternal puncture were of considerable value for this purpose. Cases with a reversal and most cases with a persistent positive venom reaction do well after splenectomy, in the latter the venom reaction becomes negative after operation. There are cases with persistent positive intracutaneous reactions that do not improve after splenectomy. The appearance of a violent reaction from intracutaneous venom injection, such as an excessive hemorrhagic reaction or the appearance of bullae or exaggeration of the purpuric state, may be regarded as a definite contraindication to operation. Such reactions occur in the severe types of acute purpura mentioned above. Absence or marked diminution in the number of megakaryocytes in the bone marrow is also a definite contraindication to splenectomy.

Schönlein-Henoch's purpura is also known as Frank's hemorrhagic capillary toxicosis or peliosis rheumatica. In this condition there are various degrees of purpuric eruptions on the skin, as well as polyarthritides. Although the treatment is symptomatic, a few cases have apparently responded to moccasin venom. According to Rosenthal, tonsillectomy may be of value in the chronic form.

In the so-called "endocrinal ecchymosis" often seen in women, good results have been obtained in a number of cases with moccasin snake venom. Some patients with Schamberg's disease and Osler's hereditary familial telangiectasia, as well as with Majocchi's disease, have been treated by means of snake-venom injections. In a number of cases there was apparently a good therapeutic result following the injections. In others, especially in Osler's disease, the venom therapy had very little influence on the course of the epistaxis.³³

The clinical use of snake venom has been made on a more or less empiric basis. It is possible that the therapeutic effects of successive small doses given over a long period are due to the development of agents that resisted the destructive action of the toxins. It is also possible that some element in the capillary walls, such as that described by Chambers and Zweifach,⁴ may be so changed that the capillary resistance is affected. So far as thrombocytopenic purpura is concerned, it should be kept in mind that neither the pathogenesis of this disease nor the action of the moccasin venom in decreasing capillary fragility is understood.

The discussion on capillary fragility given above presented the phenomenon as being due to several mechanisms. Hence, the finding that the capillary fragility is counteracted by any one treatment

must be qualified by the specific conditions under which the subject happens to be during such treatment.

EDITH E PARRIS, *Assistant Editor*

CASE 32511

PRESENTATION OF CASE

A seventeen-year-old high-school girl entered the hospital because of nervousness, perspiration, weakness and weight loss

Three months before admission she had noted increasing nervousness, profuse perspiration and weakness About a week later, during a pre-employment examination, she had been told that she had high blood pressure and thyroid disease and had been referred for treatment to a hospital, where examination revealed a temperature of 99°F, a pulse of 140 and respirations of 28 The blood pressure was 190 systolic, 140 diastolic, there was dyspnea without cyanosis, as well as a cold moist skin, bilateral exophthalmos with slight lid lag, slight narrowing of the retinal arteries, an enlarged heart and a Grade II apical systolic murmur The skin showed areas of macular eruptions, some of which were pustular and some healing Neurologic examination was negative except for a fine tremor The thyroid gland was not palpable During the ten-day hospital stay 15 drops of Lugol's solution had been given three times a day, but there had been no improvement in the symptoms and the basal metabolic rate, which had been +69 per cent initially, had not been changed The patient had been discharged to the outpatient department At that time attacks of paroxysmal nocturnal dyspnea with severe palpitation and insomnia had appeared A poor appetite rendered her diet inadequate, there had been a weight loss of 6 pounds in two months No history of intolerance to heat, of diarrhea or of

emotional upsets was elicited The eyes were said to have always been prominent During the next four weeks spent at home in bed and for a week after her second hospital admission she had taken 150 mg daily of 6-propyl-thiouracil After a week of treatment signs of left ventricular failure had been more definitely manifest, the patient had been digitalized, with immediate improvement, and had been maintained on 0.1 gm digitalis daily thereafter She had continued to lose weight and was readmitted to the hospital two months before entry to the Massachusetts General Hospital The physical findings had not changed The outstanding laboratory values were a white-cell count ranging between 10,000 and 11,000, with 85 per cent neutrophils, a normal red-cell count, a + test for albumin in the urine, with 1 white cell and 1 red cell per high-power field in the sediment, and a specific gravity consistently between 1.015 and 1.020, a blood cholesterol of 137 and 180 mg, a fasting sugar of 115 mg and a total protein of 6.6 gm per 100 cc and a basal metabolic rate of +79 per cent X-ray films of the skull had been normal, and those of the chest had shown cardiac enlargement and slight congestion of both lung fields An electrocardiogram had shown evidence of left ventricular strain and digitalis effect An intravenous pyelogram had revealed a double right ureter A phenolsulfonephthalein test and a serum nonprotein nitrogen had been normal The hospital course was marked by a low-grade fever and rapid pulse and respirations The blood pressure, taken three times a day and during sleep, had not varied appreciably, ranging between 200 systolic, 140 diastolic, and 190 systolic, 120 diastolic A gallop rhythm and pulsus alternans had developed, but the patient had remained ambulatory without respiratory difficulty Two months later she was referred to this hospital Physical examination revealed that the weight was 99 pounds, the normal having been 140 pounds The patient was calm and did not appear acutely ill The skin rash was still present There were palpable lymph nodes in both groins and a palpable node in the posterior cervical region The heart was enlarged to percussion A Grade II systolic murmur and a diastolic "blow" were audible in the fifth interspace at the left border of the sternum The thyroid gland was not palpable Rectal examination revealed hard fecal material

The temperature was 99°F, the pulse 144, and the respirations 30. The blood pressure was 180 systolic, 120 diastolic, in the left arm and 210 systolic, 150 diastolic, in the right arm.

Examination of the blood showed a red-cell count of 4,200,000, with a hemoglobin of 11.3 gm. The urine persistently showed a + to +++ test for albumin, and the sediment contained a moderate number of casts and 2 to 20 white cells per high-power field. A stool was guaiac negative. X-ray examination of the chest showed the heart to be greatly enlarged. The thyroid region was normal, and no substernal mass was visible. The esophagus was not deviated. One day later a plain film of the abdomen showed barium in the right side of the colon and a large amount of air in the rest of the colon.

An electrocardiogram disclosed a rate of 120, with normal sinus rhythm, the PR interval equaled 0.16 and the QRS complex 0.05 second, with normal voltage. There was a low T₁, a slightly inverted T₂, and an inverted T₃. The blood chloride was 96 milliequiv per liter. The protein, cholesterol, non-protein nitrogen, fasting blood sugar, calcium, phosphorus and alkaline phosphatase were normal. The glucose-tolerance curve (oral) was 93 mg per 100 cc fasting, 154 mg after thirty minutes, 146 mg after sixty minutes and 67 mg after 120 minutes. The corrected sedimentation rate was 0.93 mm per minute. The urea clearance was normal. The basal metabolic rate was +62 per cent.

In the hospital there was a persistent temperature of 99 to 100°F. The pulse and respirations were rapid, and the blood pressure was continuously elevated. The gallop rhythm heard previously was still present, and the neck veins pulsated. The circulation time (arm to tongue) was 15 seconds. The patient was cheerful and subjectively well until the end of the first hospital week, when she had a two-day episode of cramping abdominal pain and constipation without nausea or anorexia. The pain disappeared, but the constipation remained despite enemas and cathartics. Hard, lobular masses were palpated in the midabdomen and left lower quadrant. Proctoscopy revealed no fecal or tumor masses.

On the thirteenth and sixteenth hospital days x-ray films revealed a large amount of barium mixed with intestinal contents obscuring soft-tissue details in the abdomen. There were distention of the lower abdomen and mild paraumbilical tenderness. On the seventeenth day cramping pain again began, and the patient vomited several times. Distention increased, and peristalsis decreased. Additional enemas had no effect. A small amount of barium introduced by rectum showed an obstructing mass in the sigmoid. Its nature could not be determined, although it was thought to represent impacted feces. Some barium escaped around it into the colon. On the eighteenth and nineteenth days the white-cell count rose to 22,600. The temperature remained

at 102°F, the pulse became feeble, and peristaltic sounds disappeared. The blood pressure stayed high. It was decided to perform a cecostomy. At operation the cecum was greatly distended. A tube was inserted after deflation. The patient then began to vomit persistently and expired, apparently after aspiration of vomitus.

DIFFERENTIAL DIAGNOSIS

DR PAUL D. WHITE: When I read this case over, it looked like one for the book. I might add that Dr. Graybiel and I some day hope to publish a volume of unusual cases and rare types of heart disease.

One thinks of infection to account for the symptoms in a patient of this age. Another condition to account for them is thyrotoxicosis. Psychoneurosis is a possibility, but I should put infection and thyrotoxicosis first.

The pulse rate was out of proportion to the other findings except for the blood pressure. The combination of marked tachycardia and marked hypertension is unusual in either thyrotoxicosis or hypertension.

The skin showed areas of macular eruptions, some of which were pustular and some healing. That finding is confusing. Why it occurred, I have no idea. I do not know whether it fits in with my final diagnosis.

There is no statement whether the paroxysmal arrhythmia, auricular fibrillation or paroxysmal tachycardia had persisted. Thus, we have a patient with marked hypertension who could have had acute heart failure even without arrhythmia.

I do not know whether the prominence of the eyes was marked or simply a slight congenital exophthalmos with a slight lid lag. Therapy was evidently aimed at thyrotoxicosis, but left ventricular weakness became manifest, and despite the persisting tachycardia and hypertension, digitalization helped the symptoms of heart failure.

This is a characteristic record, I judge, of a hypertensive heart, without the need for diagnosis of any other kind of heart disease. At first, there was no evidence of renal insufficiency or any serious structural abnormality of the kidney. On admission the patient had lost a great deal of weight—over 40 pounds.

There is no statement regarding the appearance of the skin rash on admission. I suppose that it had the same appearance as previously.

DR TRACY B. MALLORY: Can you describe the rash better, Dr. Beckman? Did it look like acne?

DR WILLIAM BECKMAN: No, it was macular, with flat reddish lesions. It looked somewhat like a phenobarbital rash.

DR WHITE: Was the patient receiving phenobarbital?

DR BECKMAN: No.

DR WHITE: Were the lesions large?

DR BECKMAN I thought that they were definitely abnormal, about 2 cm in diameter

DR WHITE The murmur had not changed There was a diastolic blow, but I judge that it was rather slight Whether it could be attributed to the failure of the aortic valve to hold against such a high pressure as stated, I do not know, but I rather suspect that that is the answer, rather than endocarditis

I assume that there was a good enough pulse in the feet, however Can you answer that, Dr Beckman?

DR BECKMAN Yes, there was

DR WHITE That helps to rule out possible deformity in the aorta, in particular, coarctation, which can be attended by a difference of the blood pressures in the two arms I should also like to know if that blood-pressure difference was noted elsewhere, or before or after this occasion It was probably not a remarkable finding

DR BECKMAN I thought that it was not remarkable I do not remember being impressed by it at all

DR WHITE One does find pressure differences normally in the two arms

If the test is repeated, the blood pressure in the same arm is sometimes different the second time from that on the first occasion I should not pay too much attention to that one observation

Renal involvement was more evident on admission to this hospital

A thoracic goiter—that is, a thyroid tumor in the mediastinum—was being looked for

Was the barium in the colon that which was previously put in for study of the esophagus?

DR BECKMAN So far as I know

DR WHITE The electrocardiogram was not diagnostic, nor was it a remarkable record The T waves could have been low because of tachycardia

We now come to the beginning of the symptoms in the abdomen, where there is indication of some trouble According to the record, there appeared to be an unusual amount of air in the colon

Was new barium given, or were the latest x-ray findings due to the old barium?

DR BECKMAN It was the same barium

DR WHITE It had been in the gastrointestinal tract a long time In other words, there was more and more evidence of intestinal obstruction

In the discussion of the diagnosis, certain things are obviously important clues These include the high basal metabolic rate, which must be taken into consideration, the high blood pressure with cardiac enlargement and failure resulting therefrom and the rapid pulse Much effort was made in an unsuccessful attempt to find a thyroid tumor somewhere The picture, of course, does not fit thyrotoxicosis We do not expect to find hypertension in thyrotoxicosis, although other findings do fit—namely, the tachycardia, high basal metabolic rate,

tremor, exophthalmos and weight loss This patient certainly does not fit the picture of Cushing's disease Except for the hypertension and heart enlargement and failure therefrom, the picture does not fit essential hypertension We must put together the hypertension and the signs that do not go with hypertension as a rule The abdominal symptoms, and signs that appeared toward the end strongly, suggest some degree of intestinal obstruction

I believe that it is possible to fit most of this picture together,—although there are some clues that I am unable to make use of, such as the skin lesions,—if we make a diagnosis of an adrenomedullary cell or chromaffin-tissue tumor, which would be called a pheochromocytoma if located in one of the adrenal glands or a paraganglioma if occurring outside in the sympathetic ganglions Some of these tumors grow to a large size, but I am not familiar with them I have seen little of this disease, although a good many cases have been well described Such tumors may conceivably obstruct the lower gastrointestinal tract, especially if outside the adrenal gland itself The combination of symptoms and signs certainly fits the picture of what might be called the suprarenal sympathetic syndrome tachycardia, hypertension, high basal metabolic rate, weight loss, tremor and so on I cannot explain the skin lesions, however, by this condition I thought of disseminated lupus as an explanation of the skin lesions, but the rest of the case does not back that up

My diagnosis therefore is pheochromocytoma or paraganglioma, probably the latter, leading to marked and malignant hypertension with resulting cardiac enlargement and failure and in some way causing terminal intestinal obstruction In patients with chromaffin-tissue tumors, paroxysmal attacks of hypertension and other symptoms frequently occur, but the hypertension often remains constant

DR OLIVER COPE I should like to add certain information that is not in the record I think it is only fair to place before Dr White some of the complexities that faced the clinical service I saw the patient because she was sent to this hospital with a question of one of the diagnoses that Dr White has made—that is, pheochromocytoma The other hospital had considered and rejected thyrotoxicosis Five days after admission to this hospital the patient developed a pericardial friction rub It was pointed out to me by one of the medical residents, it was clear and distinct Am I correct, Dr Beckman?

DR BECKMAN Yes, it was there

DR COPE It was assumed that pericarditis was present

DR J H MEANS Dr Cope, you are familiar with the pseudopericardial friction rub?

DR. COPE It was not one of the pseudopleuro-pericardial friction rubs heard over the pulmonic area, this pericardial rub was heard over the entire precordium and loudest over the apex impulse. It was not influenced by respiration. We went through that carefully. One physician, however, thought that it was not a pericardial rub.

DR. MEANS It is well known that in moderate thyrotoxicosis a noise can be heard over the heart that sounds like a pericardial friction rub toward the base. We have been familiar with that for years. The thing to remember is that it is of no importance because if the thyroid gland is removed and the thyrotoxicosis cured, the noise disappears. I do not know how it is produced. This patient had a high metabolic rate, and I wonder if the kind of noise you are talking about might not have been of that variety.

DR. WHITE It was probably due to bulging of the artery. A pericardial friction rub can be present without pericarditis.

DR. MEANS Believe it or not, I had written down pheochromocytoma, question mark, before Dr. White mentioned it. I do not know whether that is the correct diagnosis. I had also thought of lymphoma, however. It did not satisfy me, but it had to be thought of. I thought of leukemia, but there was no indication of leukemia.

DR. JOSEPH C. AUB The white-cell count was suggestive.

DR. MEANS I should approach this case as Dr. White did. Because of the similarity of the symptoms to those of thyrotoxicosis, a number of methods for detecting that condition must be used but there is no evidence that they were employed in this case. The blood iodine, for instance, would have been of importance.

DR. BEVERLY TOWERY It was normal.

DR. MEANS If normal, it weighs heavily against thyrotoxicosis. Another method is to observe the uptake of radioactive iodine by the thyroid gland. The hyperplastic gland takes up more than the normal.

DR. RULON W. RAWSON That was done, and the result was within normal limits.

DR. MEANS I agree with Dr. White. The only other test that might have been used is creatine tolerance. I think that thyrotoxicosis can be ruled out, in spite of the marked elevation of the metabolic rate. I wrote down several causes of high metabolic rate. One was thyrotoxicosis, another leukemia, another fever, another a hole in the eardrum, and still another that the patient was apprehensive every time the apparatus was used and that the test was not basal. Another possibility is an abnormal amount of adrenaline. I remember that some years ago, when my metabolic rate was being tested every day for an experiment, it was always normal until one day it was +40 per cent.

The technician asked if I had suddenly developed Graves's disease? I said no. I did not have Graves's disease, but that on the way to the laboratory I had had an alteration, which raised the rate. I apparently had shot myself full of adrenaline in the alteration. I think that it would be reasonable to explain the high metabolism in this case on an excess of the only hormone other than thyroxine that I know of that has a characteristic calorogenic action, namely, adrenaline, which is a quick-acting hormone, whereas thyroxine is a slow-acting one. Adrenaline might be discharged continuously and thus give a sustained high metabolism. A tumor of the medulla of the adrenal gland might cause a continuous output of adrenaline, and I agree entirely with Dr. White that that is probably the diagnosis in this case. I cannot see any other diagnosis that could fit this combination of hypertension and hypermetabolism in the absence of thyrotoxicosis. If there is something else, it has not entered my field of consciousness.

One other point about a pheochromocytoma: we used to be taught that the characteristic picture was a series of seizures or hypertensive crises in which the patient might die, but that between these seizures the blood pressure was normal. Dr. White has told us that that is not true, hypertension may be continuous.

DR. AUB There are several things concerning the adrenal glands that do not satisfy me, but at the same time the things that ought to be considered do not give a high blood pressure. Also, I am puzzled by the rash and the pericardial friction rub. I believe that we must think of either lymphoma or aleukemic leukemia to explain this picture.

DR. MEANS Dr. Aub's point is well taken, and he may turn out to be correct, but it is difficult for me to believe that a lymphoma or a leukemia would produce such a marked elevation of the metabolic rate. My recollection is that Dr. Minot and I once found a fairly close parallel between the white-cell count and the metabolic rate. I do not believe that the ordinary case of lymphoma, with a more or less normal blood picture, has more than a moderate rise in metabolic rate.

DR. AUB That may be true of lymphoma, but aleukemic leukemia may cause a high metabolic rate.

DR. MEANS I suppose that a great deal was going on in the marrow.

DR. MALLORY Dr. Beckman, have you anything to say?

DR. BECKMAN I can only say that this case illustrates the harm of ignorance. I was impressed by the fact that the patient seemed to be so sick. She had lost 40 pounds and had developed heart disease that had gone rapidly into failure during the three months, and I thought that it was probably something akin to lupus erythematosus or rheumatic fever, with severe rheumatic carditis, and was willing to rule out the diagnosis of pheochromocytoma.

DR RAWSON There are three things that I should like to point out. Patients with leukemia and a high metabolic rate studied at the Huntington Hospital usually had large spleens, and the highest basal metabolic rates were observed in patients with so-called "agnogenic myeloid" metaplasia. The white-cell counts were 20,000 or less, with large spleens. I got the impression from some of the patients that a high basal metabolic rate was more related to the size of the spleen than to the white-cell count.

I also want to point out, as Dr Cope has said, that this girl had a friction rub off and on. If the diagnosis of pheochromocytoma is made I think that that, rather than obstruction from tumor, would explain the constipation—the reaction of adrenaline on the smooth muscle of the intestinal tract.

DR. EDWARD F. BLAND I agree with Dr Beckman that this patient was profoundly ill. She presented the picture of severe systemic disease and suggested the possibility of lupus erythematosus without the skin lesions. We also considered severe rheumatoid arthritis and rheumatic fever. The service was more inclined to rheumatic fever, but that possibility did not impress the cardiac group. Dr White's interpretation of the diastolic murmur from its description in the record is perfect. There was a slight diastolic blow along the left sternal border. I saw the patient only once during cardiac rounds and two studies suggested themselves, but I judge that she was too profoundly ill to undertake them. One was a pneumogram, and the other a histamine test. The latter is not without danger.

DR BECKMAN The first one was not done because we could not get rid of the barium.

DR WILLIAM C. BURRAGE I was asked to see this patient because, with Dr Halsted and other members of the Sixth General Hospital, I had seen a case of pheochromocytoma in the military service. The patient was a thirty-two-year-old paratrooper who was being studied for a possible duodenal ulcer. We did a histamine test, employing 0.5 mg of histamine, whereupon he promptly went into apparent collapse. The blood pressure, instead of showing hypotension, was 285 systolic, 160 diastolic. We knew that it had been normal on the previous day. In the course of two or three hours it dropped to normal, but for about two weeks following the episode the patient was quite ill. Electrocardiograms showed minor changes in the T waves and elevation of the ST segment. It is interesting that in 1935, the Mayo Clinic presented an article on the use of histamine intravenously to prove the presence of pheochromocytoma.* Three cases were reported in which the patients were given 0.025 mg of histamine phosphate intravenously, with a systolic rise of at least 120 mm of mercury and with

a concomitant rise in diastolic pressure. It was believed that that was certainly a fair provocative test. We ourselves subsequently repeated the test with 0.02 mg of histamine intradermally and obtained an elevation of 160 mm in the systolic blood pressure. It is fair to say, however, that these patients are subject to sudden death and that the use of this test is not without danger.

DR. CHESTER M. JONES Is it not true that in palpating one of these tumors too vigorously there is a risk as great as the injection of histamine? That risk should be considered before palpation is done.

DR MALLORY I should think so, and the danger also holds for air injection, without which one cannot discover which side the tumor is on.

CLINICAL DIAGNOSES

Intestinal obstruction
Lymphoma?
Rheumatic heart disease?
Pheochromocytoma?
Hypertension

DR WHITE'S DIAGNOSES

Paraganglioma, or pheochromocytoma, with hypertensive heart disease and congestive heart failure
Intestinal obstruction (terminal)

ANATOMICAL DIAGNOSES

Pheochromocytoma left adrenal gland
Cardiac hypertrophy
Pulmonary congestion and edema
Dilatation of cecum and ascending and transverse colon, with fecal impaction
Fibrous pleuritis, old
Emaciation

PATHOLOGICAL DISCUSSION

DR MALLORY Autopsy showed a tumor of the left adrenal gland, between 6 and 7 cm in diameter. On its surface were tiny fragments of cortex. The tumor, arising in the medulla, had grown expansively and had broken the cortex up into scattered fragments, apparently lying in the capsule of the tumor. The heart was markedly hypertrophied, weighing 420 gm, which for a girl of seventeen is extremely large. There was no trace of pericarditis to justify the friction rub. The kidneys were apparently normal grossly and histologically. The tumor histologically was a characteristic pheochromocytoma. There was no mechanical intestinal obstruction. The bowel still contained many large inspissated masses of feces, and the intestinal symptoms were evidently purely those of a maximal grade of constipation.

*Roth, G. M., and Kvale, W. F. Tentative test for pheochromocytoma (using histamine injections). *Am J M Sc* 210: 653-660, 1945.

CASE 32512

PRESENTATION OF CASE

A fifty-nine-year-old insurance executive entered the hospital because of an attack of "indigestion" followed by dyspnea and vomiting.

Six months previously the patient had had an attack of chest pain radiating down the left arm. A physician took an electrocardiogram, but details of the results were not available. The patient was placed on strict bed rest for six weeks, after which he was gradually permitted to get up and move around for the next week and a half. At about that time he had an episode of mental depression and a fear of going anywhere. No objective neurologic signs were noted. Three and a half months later, he started going to his office for two hours daily and gradually increased the time until just before the admission, when he was spending five and a half hours a day at the office.

Nineteen hours before admission the patient was awakened by an attack of "indigestion" but the pain soon moved up into the chest and radiated down the left arm, three hours later he became short of breath and vomited. Two and a half hours later he began to spit up frothy red material and his breathing sounded as if the throat were "full of water." A physician found the blood pressure to be 70 systolic, 40 diastolic, and the pulse to be 130, 15 mg of morphine was given. Nine hours later, 12 mg of Purodigin was administered. About an hour before admission the blood pressure had risen to 100 systolic, 70 diastolic, but the pulse remained at 130 and the patient was orthopneic. There were a few rales in the lungs, the heart sounds were distant, and there was a regular, gallop rhythm. At about that time bloody urine was passed.

On admission the heart was slightly enlarged to the left, and the sounds were faint and distant, with a regular gallop rhythm of 140. Persistent moist rales were heard throughout both lung bases, extending half way up the scapulas. The liver was barely palpable and questionably tender. There was no edema of the lower extremities.

The blood pressure was 100 systolic, 80 diastolic. Examination of the blood showed a hemoglobin of 16.0 gm and white-cell count of 23,000, with 92 per cent neutrophils. The urine had a specific gravity of 1.020 and gave a + test for albumin. The sediment contained frequent hyaline casts, rare red cells and 3 white cells per high-power field. X-ray examination revealed extensive, mottled, hazy density throughout both lungs, most pronounced in the middle and lower lung fields. The left leaf of the diaphragm and the outline of the left side of the heart were obscured.

An electrocardiogram (cardiette) taken on admission revealed a sinus tachycardia of 180. Low QRS voltage was greatest in Lead 3, where it measured 2.5 mm. There was an S wave in Lead 1 equal to

1 mm, and right-axis deviation was present. T_1 and T_{CF_1} were slightly inverted, T_2 - and T_{CF_2} were flat, T_3 was diphasic and T_{CF_3} was upright. There were small R waves in Leads CF_2 and CF_4 and no R wave in Lead CF_1 . A Q wave equal to 3 mm was noted in Lead CF_1 . A second tracing taken the next day revealed a somewhat increased rate, the T wave in lead CF_1 had become much lower.

On the second hospital day a venesection was performed, and 500 cc of blood was withdrawn. This resulted in improved breathing, but during the same evening breathing again became difficult and moist bubbling rales were heard throughout both lung fields. The pulse became weak, and the apical pulse was 150. The downhill course continued, two days later the blood pressure was 94 systolic, 80 diastolic. The pulse was 140 and weak but regular. Respirations were 40, and there was slight cyanosis despite oxygen administration. The patient died quietly on the fourth hospital day.

DIFFERENTIAL DIAGNOSIS

DR HOWARD B SPRAGUE This record appears to be fairly straightforward, but the history is often deceptive. The first episode seems to be quite clear cut. Out of a clear sky, six months before the fatal illness, this man had had an attack of pain in the chest radiating down the left arm, it was sufficiently characteristic to suggest that he should have an electrocardiogram, whose results we do not know, but he received the textbook treatment for coronary thrombosis with myocardial infarction — bed rest for six weeks. The mental depression and fear of going anywhere are frequent in patients recovering from myocardial infarction. This patient, however, was able to go back to his work. We do not know whether, during the next period before the fatal attack, he had residual difficulties, such as angina on effort and dyspnea. He was then awakened by an attack of indigestion. It is noticeable that on each occasion there was the same pattern of indigestion, dyspnea, vomiting and radiation of pain down the arm. Shortly thereafter the patient developed pulmonary edema, with frothy sputum and a marked fall in blood pressure. Throughout this final fatal episode he had an extremely rapid tachycardia and a gallop rhythm was prominent. There was evidence of left ventricular failure and a marked increase in the rate, so that one can assume that two mechanisms produced the gallop rhythm, which was probably a "summation gallop rhythm," as it is called — namely, a third sound mechanism during the early stage of left ventricular filling superimposed on whatever sound is produced by auricular contraction.

At that time bloody urine was passed. I do not know whether that is significant, but it was later revealed that there were red cells in the sediment. The patient entered the hospital in shock, with faint and distant heart sounds, a low blood pressure, a

gallop rhythm and tachycardia. May we see the x-ray films?

DR JAMES R. LINGLEY: There is extensive density on both sides of the chest, as described in the record. The density is hazy and involves the greater portion of both lungs. I think that the appearance is consistent with edema. I interpreted these films and was disturbed by this shadow at the left base, which I thought could possibly be due to an infarct, but so much edema is present that I do not believe that one can be certain.

DR SPRAGUE: Can you say anything about the heart size? The record states that the heart was slightly enlarged clinically.

DR LINGLEY: I think that it probably was.

DR SPRAGUE: The high white-cell count and the urinary findings seem to be consistent with a combination of shock and cardiac failure, although we must think of renal infarcts in such a situation. The electrocardiogram, which we must take as described in the record, is confusing. When we have, as we assume to be true in this case, more than one myocardial infarction, the electrocardiogram often loses its characteristic pattern, and the findings produced by the previous infarction are probably masked by the second one. A definite finding is the low-voltage electrocardiogram, with inversion of the T waves in Leads I and CF₆, which is out in the axilla, and rather small R waves in the leads taken to the left of the sternum and at the apex, there was no R wave in Lead CF₆. These findings are consistent with myocardial infarction of the anterior and apical type, probably rather lateral in position. I shall discuss that later. If we can assume that the T waves in Lead CF₆ became lower, at least extension of the electrocardiographic abnormalities toward the midline is indicated.

A venesection was performed. The patient's breathing was improved, but he died on the fourth hospital day.

There are a few things that bother me. In the first place, the pulse rate went up to 180, and the next day it was somewhat faster. That is an extreme degree of sinus tachycardia — in other words, a normal mechanism. It suggests that this was ectopic auricular tachycardia, perhaps an auricular flutter. Although normal sinus tachycardia can occur at this rate and since in this case the pulse varied apparently in steps between 130 and 180, this was probably a sinus mechanism rather than an abrupt change from a rapid ectopic tachycardia to a sinus tachycardia that was considerably slower. The electrocardiogram seems to me to reflect an infarction involving the anterior and apical regions of the heart, later complicated by posterolateral involvement. The T-wave depressions in Lead I and in the chest leads characteristic of anterior and apical infarction may be partly masked by changes in the posterior wall of the heart. A patient may die of myocardial infarction with a more normal

looking electrocardiogram just before death than during the time of the first infarction. Because the auricle in this case showed such an extreme irritability, was there also auricular infarction? Auricular infarction is an extremely difficult condition to diagnose. It seems to be associated with abnormalities in auricular rhythm, such as auricular fibrillation, auricular flutter and changes in the T waves of the auricle. The T waves of the auricle are not ordinarily seen unless auriculoventricular block is present to separate the auricular complexes from the ventricular, and to allow one to see the normal inverted T waves. In a few cases of auricular infarction described in the literature these auricular T waves have become upright.

The question of pulmonary infarct always arises in cases of this sort. Statistically we are justified in saying that pulmonary infarction occurs. I bring the possibility of pulmonary infarction into the discussion only to reject it. At least, this sudden episode suggests pulmonary edema and left ventricular failure. There had been no pain in the chest, and the character of the sputum was consistent with acute pulmonary edema. It is possible that there was a renal embolism, which brings up the question whether or not following the original infarction a mural thrombus of the ventricle was a source for emboli. One would certainly be brave to suggest that six months after an infarction this man had a coronary embolus from the left ventricle. The first case, I believe, in which the diagnosis was suggested clinically was described by Dr Louis Hamman* shortly before the war, the patient, a young woman without heart disease who was thought to have coronary embolism from thrombi in the pulmonary veins during a respiratory infection, recovered, and the diagnosis was not proved. It is much more probable that in the case under discussion there was an extension of a severe degree of atherosclerosis and occlusion of the coronary tree. I therefore believe that the patient had a myocardial infarction involving the left ventricle, probably the anterior apical portion first, that he later had an extension — probably laterally — that resulted in a wide degree of infarction of the left ventricle, that the findings do not suggest septal involvement unless it was in the anterior part of the septum and that there were probably mural thrombi of the left ventricle, there is a vague possibility of involvement of the auricle by infarction and of infarcts in the kidney.

DR ROBERT S. PALMER: Does the right-axis deviation in the electrocardiogram make you think more seriously of pulmonary embolism than of infarction?

DR SPRAGUE: Of course that entered my mind, but a high percentage of patients developing anterior infarction have a shift of the electrical axis to the right. It is true that those who have a posterior

*Hamman L. Coronary embolism. *Am Heart J* 21:401-422 1941

infarction have a higher percentage of shift of the axis to the right, but I have decided against infarction of the posterior part of the septum. The right-axis deviation was possibly due to one of at least three mechanisms. I was willing to discard pulmonary embolism as the cause.

DR. BENJAMIN CASTLEMAN: Is not right-axis deviation in cases of myocardial infarction most frequently due to septal involvement, with bulging into the right ventricle?

DR. SPRAGUE: Such a situation is likelier with posterior involvement of the septum. There has been some argument about the mechanisms of this shift of axis. I should hesitate to make a diagnosis of posterior septal infarction, because we have no indication of bundle-branch defect or auriculo-ventricular block, which would be fairly likely.

DR. LOWREY F. DAVENPORT: In a case that came up for discussion on the surgical service the question was raised whether one is likelier to find coronary infarction with a normal electrocardiogram or pulmonary infarction with a negative x-ray examination. What is your experience?

DR. SPRAGUE: I think that pulmonary infarction with a negative x-ray examination is more probable.

DR. TRACY B. MALLORY: Do you want to challenge that remark, Dr. Lingley?

DR. LINGLEY: No.

CLINICAL DIAGNOSES

Coronary heart disease

Acute myocardial infarction

DR. SPRAGUE'S DIAGNOSES

Old coronary occlusion, with infarction of anterior apical region of left ventricle

Fresh coronary occlusion, with infarction of posterolateral area of left ventricle and mural thrombi of left ventricle

Possible infarction of anterior part of inter-ventricular septum, with auricular infarction and renal infarcts

ANATOMICAL DIAGNOSES

Coronary sclerosis, with recent thrombosis of circumflex branch of left coronary and old recanalized thrombosis of descending branch of left coronary artery

Myocardial infarction, recent, massive posterolateral aspect of left ventricle

Myocardial infarction, healed, apical, with mural thrombus

Arteriosclerosis, generalized, moderate

Pulmonary edema, acute, massive

PATHOLOGICAL DISCUSSION

DR. MALLORY: Autopsy showed a hypertrophied heart, which weighed 500 gm., and as Dr. Sprague

predicted, evidence of two episodes of infarction of the myocardium. The anterior surface of the left ventricle and the adjacent part of the inter-ventricular septum showed an old dense fibrous scar consistent with an infarction six months previously. Overlying this area was a large mural thrombus, which was partially organized. The fresh infarction was in the posterolateral aspect of the left ventricle, and the two infarcts together involved approximately two thirds of the entire ventricle. Little living musculature remained. There were two points of occlusion in the coronary arteries, which could be correlated with the separate myocardial lesions. In the descending branch of the left coronary artery was an old area of narrowing with calcification that seemed to have a trace of recanalization no wider than 0.5 mm. in diameter, in the circumflex branch a fresh thrombus, about 1 cm. in length, was still red and had evidently caused the second episode.

The lungs were rather interesting. They were markedly and diffusely edematous, the combined weight being 1900 gm. They did not present the usual appearance of acute pulmonary edema of cardiac origin. The transudate into the alveolar sac is ordinarily a thin watery fluid, such as the frothy fluid coughed up by this patient at the initial episode. At the time of death, however, the alveoli were filled with a protein-rich fluid, which in fixation coagulated almost like thyroid colloid and in which large numbers of red cells were found. There were a number of tiny thrombi in the small arterioles, but no gross pulmonary emboli. Nothing was found that could be called an infarct of the lung, but I believe that the patient did have a shower of minute pulmonary emboli. Since no gross infarcts were found we did not explore the leg veins in this case. I cannot say what the source was, but I think that sometime during the last day or two of life, a shower of minute emboli probably changed the character of the pulmonary findings, although it did not produce frank infarction. Because of the hematuria we were interested in the kidneys but found nothing whatever.

DR. SPRAGUE: These pulmonary findings could not be explained on a thrombotic basis?

DR. MALLORY: Perhaps they could be. I am unable to decide, but at any rate it is an unusual phenomenon.

DR. SPRAGUE: You have not seen that with ordinary congestive failure?

DR. MALLORY: These lungs looked more like those seen in acute nephritis than the lungs of cardiac failure.

DR. SPRAGUE: The posterior septum was not involved?

DR. MALLORY: No.

CHRISTMAS 1946

THERE can be no beginning without an ending, no ending without the commencement of something new. A successful termination of the process of gaining an education in a properly constituted hall of learning was once termed, by some inspired educator, a commencement. It is, for the individual, the ending of a probationary period and the beginning of a new phase of personal existence, the conclusion of a somewhat rudimentary activity and the inauguration of a broader experience. Life is full of commencements and graduations and closing of books and opening of new accounts and endings and beginnings.

And so Christmas, which marks the beginning of a new era, annually reaffirmed, marks also the end-

ing of an older period that has made its contributions to the progress of man and is ready to depart.

Christmas, not so many years ago, was considered a pagan festival by our unctuously righteous forefathers, and indeed it was, in its fundamentals, just that. Marking approximately the end of the season of shortening days and the almost imperceptible beginning of the sun's return, it was an important date on the calendar in the forests of northern Europe, where the days were short and cold and the nights were long and dark.

Its Christian significance goes back to the second century A.D., when the birth of Christ began to be celebrated, and it is reported that the Emperor Diocletian, learning that a number of Christians were commemorating this blessed event, set fire to the building, whereby they all perished.

The Christian cycle developed in the fifth to eighth centuries, in which the winter solstice, celebrated by all nations as marking the renewal of life in nature, was appropriately accepted by the Church as the time to celebrate also the dawning of a new spiritual light on the earth. Since that period we have had dual forms of observance: the deeply religious ritual of the Christian Church, combined with the merrier pagan reaction to a faint promise of spring—a convenient association, but frowned on by our ancestors, the Puritans.

The customs of Christmas, of which the Merry Christmas that we now wish our readers is not the least important to us, are too firmly fixed for their origins to detract from the supreme value of the day. It is the day of that good will which may yet allow us to live together in harmony. It is the day on which we settle the accounts of a dying year and look forward, perennially optimistic, to a new year, of which more anon.

FALSE PROPHET

ON November 11, 1943, the *Journal* acknowledged the passing of another milestone in the long struggle to ensure a safe and satisfactory milk supply for the population of the Commonwealth. This particular milestone was a newly adopted regulation of the Boston Health Department, effective on September 30 of that year, putting an end to the sale of raw milk in the City of Boston, regardless of its source.

Some years earlier the sale of all raw milk in the city, unless certified by the Boston Medical Milk Commission, had been prohibited, in 1930 the commission, on its own initiative and against the opposition of the American Association of Medical Milk Commissions, had voted to permit the pasteurization of milk on farms under its certification. The association now accepts the pasteurization of certified milk, and the Boston commission requires it

And so the slow steps have been taken leading toward as safe a milk as can be procured for as large a percentage of the population as possible, with the knowledge always before us that bacterial contamination makes milk unsafe—contamination not only with the tubercle bacillus and *Brucella abortus* but also with the streptococcus, the typhoid bacillus, the dysentery-producing organisms and many others

It leaves us aghast, therefore, to read in the November 5 issue of the *Boston Traveler* in "Personal Health Service," a column contributed by William Brady, M.D., not only the author's unique classification of milk but also his reasons for defending that classification against all comers

Dr Brady's classification of the grades of milk is as follows: first choice—certified milk, second choice—Grade A raw milk from a tuberculin-tested herd, and third choice—any fresh milk, scalded or boiled one minute. "Any old milk," according to Dr Brady, "regardless of its source, quality or purity, is made safe for infant, child, invalid or adult by scalding, that is, by bringing to a boil and boiling for one minute." (The accepted definition of scalding is bringing to a boil, the one minute is Dr Brady's contribution.)

Dr Brady's two reasons for placing raw milk in first and second places (he apparently assumes that certified milk is necessarily raw) are that undulant fever from ingested milk is a rare disease, and that

raw milk in his opinion tastes better than parboiled or scalded milk. Although at one point he mentions pasteurized milk, indicating that he is aware of its existence, it nowhere enters into his classification. It is not by chance that all the milk now legally sold in Boston and a large percentage of that distributed elsewhere in the Commonwealth are pasteurized.

The pasteurization of milk, even of clean milk, needs no justification in these columns, nor is it possible

anywhere to justify the use of dirty milk, even when sterilized, if clean milk can be made available. Supposedly pure milk may become contaminated with pathogenic organisms, and pasteurization makes assurance of purity doubly sure. This fact has been accepted by public-health authorities for years.

Dr Brady is certainly welcome to his own opinions on these matters so long as he keeps them

to himself. When he uses the pages of newspapers to advocate dangerous and discarded principles, however, some effort should be made to protect the public from his irresponsible doctrines.

MASSACHUSETTS MEDICAL SOCIETY POSTWAR LOAN FUND

The Postwar Loan Fund has been set up, and all discharged medical officers who were members of the Massachusetts Medical Society in good standing at the time of their entry into the service may apply for loans from this fund. For further information apply to:

MASSACHUSETTS MEDICAL SOCIETY DEATHS

BARKER—Williston W. Barker, M.D., of Dorchester, died November 26. He was in his sixty-fifth year.

Dr Barker received his degree from Harvard Medical School in 1906. He was a member of the New England Pediatric Society and a fellow of the American Medical Association.

His widow, two sons and a daughter survive.

HUTCHINSON—Charles M. Hutchinson, M.D., of Cambridge, died November 26. He was in his seventy-seventh year.

Dr Hutchinson received his degree from Dartmouth Medical School in 1894. He was a fellow of the American Medical Association.

His widow and a daughter survive.

MORGAN—Charles R. Morgan, M.D., of Medford, died November 28. He was in his sixty-ninth year.

Dr Morgan received his degree from Tufts College Medical School in 1907. He was a fellow of the American Medical Association.

His widow, two sons and three daughters survive.

MOULTON — Allen T Moulton, M D, of Boston, died November 22 He was in his fifty-seventh year

Dr Moulton received his degree from University of Maryland School of Medicine and College of Physicians and Surgeons in 1911

His widow survives

PHELPS — John S Phelps, M D, of Lynn, died December 3 He was in his eighty-first year

Dr Phelps received his degree from Harvard Medical School in 1893

A niece and two nephews survive

ROY — Joseph N Roy, M D, of Webster, died March 19 He was in his seventy-fifth year

Dr Roy received his degree from Baltimore University School of Medicine in 1902 He was a fellow of the American Medical Association

A HUNDRED YEARS AGO

A circular has been issued by a committee of the Berkshire Medical District, addressed to the profession of Massachusetts, in which are set forth, in plain language, the grievances of the practitioners on the west side of the mountain They apprise all whom it may concern that an application will be made to the Legislature, the next session, praying that the Massachusetts Medical Society may be reorganized, and in default of such re-organization, that the profession in the County of Berkshire may be constituted a separate and distinct medical society The fact is, the opinion is entertained that all the essential executive officers are invariably held by persons in Boston, or near by — and as some of the malcontents have often asserted, their portion of the members are only parts and parcels of the medical machinery to hold up one or two men before the community as those whom the multitude of doctors delight to honor They say, too, that the old trick of serving out sop by giving the interior of the State a *vice*-president, occasionally — a post that no one covets — will no longer work All this has frequently been sounded in the ears of the Fellows on anniversary meetings, but it produced no amelioration, and now a desperation is manifested that will certainly re-make or break the old Society — As the Boston dentist Dr J F Flagg says, everyone who has any sympathy for human suffering and all who are called upon professionally to perform painful operations must feel desirous to avail themselves of the means of diminishing or destroying that state of consciousness which recognizes all violence done to the sensitive tissues of the body, while such operations are in process He understands, however, that the free use of the *letheon* has been ceded only to the surgeons of the Massachusetts General Hospital In spite of Dr J C Warren's admonition that the *letheon* should never be employed except under the inspection of a judicious and competent person, he asks why, if he or any other reputable practitioner wishes to avail themselves of any of the

possible effects of an article of the materia medica, they must purchase the right to use it and use it as a patent medicine? — A Fellow writing anonymously asks whether any patent has been obtained for the *modus operandi* of reconciling the principles and avowed objects of the Massachusetts Medical Society with the recent practice of some of its leading members He suggests that as new patents come out for new discoveries in medicine, the country practitioners might take turns with the city practitioners in writing the puffs and paying for the patent, exercising, of course, all due meekness and quietness while the patenting business is going on — Dr J D Mansfield of South Reading says that it seems to him not only ridiculous but absolutely wrong for any physician to adopt a course of action so entirely contrary to the spirit of the rules of the Massachusetts Medical Society as that assumed by the Boston surgeons Physicians in his vicinity, he is satisfied, will use the ether if they have occasion so to do, and if ether alone does not answer the purpose they can easily find a compound that will do as well as the *patented* vapor — Dr A L Pearson of Salem disagrees with such views Having used the new gas successfully in three cases, he believes that Dr Morton and Dr Jackson, at least, are entitled to the hearty thanks of the profession for their discovery If some hunter up of obsolete theories should prove that such a thing had before been thought of, or tried, still these gentlemen are entitled to the credit of having made it, for the first time, perfectly available to the suffering, and submitted it to the test of those competent to decide on its merits, without being content to rest its pretensions on nonprofessional credulity or popular notoriety — Dr Henry J Bigelow reports that a few days since, he tied the Femoral Artery of a patient who was unable to pay for the operation He found no difficulty in obtaining the gratuitous use of the ethereal vapor, nor could he conceive that others would in similar circumstances — We learn that in the United States with a population of 20,000,000 of people, there are about thirty medical schools, in which there are probably an average annual number of 4500 students, 1300 of whom are yearly graduated No wonder there is such a prodigious competition for professional existence — It seems that the War Department may be somewhat annoyed by persons wishing employment as surgeons in the Army What will become of all the young doctors if some outlet is not found for them? — Dr Nathan Holmes, of St Louis, Mo, announces that whiskey, or any other stimulus, freely given till there is a high pulse, will cure the bite of the rattlesnake He says that he doubts whether fifty rattlesnakes could poison a man when fully drunk — Smallpox is again creeping on toward New England Dr Thomas Sanborn of Newport, New Hampshire, reports ten cases in Goshen, all vaccinated several years pre-

virus, but probably with impure virus. In a great number of exposures to varicellous contagion, not a single one of those vaccinated on the day or previous to exposure had the varcoloid and no bad consequences resulted. — Another great discovery is announced in France by M. Pelouze, the chemist, viz, priming gun cotton with fulminating mercury. The same great man proposes to feed mankind on wood. Old bedsteads, broken chairs, and fractured table legs yield, it is said, azote enough to sustain the invading army of Mexico. — As usual there is an excellent class in attendance on the medical lectures at Yale College, the present season. The number does not equal some other institutions, but in no place is the course of instruction more perfect or thorough. — Extracted from the *Boston Medical and Surgical Journal*, December, 1846

R F

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

FREE WHOLE BLOOD THROUGH HOSPITALS

Several Bay State hospitals are now co-operating with the Massachusetts Blood Donor Program by providing free, whole blood to all patients, regardless of their financial status. (Hospitals may continue to charge their usual fee for administration.) Under this plan, the hospital blood banks operate in much the same manner as previously, except for the following changes:

Relatives of patients are asked to replace only one pint of blood for each unit required for the patient. Current donations to the hospital blood bank are considered as contributions to the state program.

The Department of Public Health sends regular supplies of whole blood to maintain these banks at a safe level; these supplies represent a return to the community of the blood donated by residents of the community through the Mobile Unit.

The list of hospitals that have adopted this program is as follows:

Burbank Hospital, Fitchburg
St. Luke's Hospital, New Bedford
Hillcrest Hospital, Pittsfield
House of Mercy Hospital, Pittsfield
St. Luke's Hospital, Pittsfield
Waltham Hospital, Waltham
Westfield State Sanatorium, Westfield
Addison Gilbert Hospital, Gloucester (to begin as soon as installation of refrigeration equipment is completed)

Any hospital desiring to set up a free, whole-blood program should work out preliminary arrangements with the local chapter of the American Red Cross. After initial plans are drawn up, the State blood laboratory should be consulted regarding final arrangements whereby the whole blood can be supplied to the hospital.

MOBILE-UNIT VISITS

The Mobile Unit of the Massachusetts Blood Donor Program will make the following visits during late December and early January:

PLACE	DATE
Wilmington	December 30 and 31
Haverhill	January 7, 8 and 9
Weymouth	January 14
Lowell	January 15, 16 and 17

BOOK REVIEWS

Acute Injuries of the Head: Their diagnosis, treatment, complications and sequelae. By G. F. Rowbotham, B.Sc. (Manchester), F.R.C.S. (Eng.). With a foreword by Norman M. Dott, M.B., Ch.B. (Edin.), F.R.C.S. (Edin.). 8°, cloth, 424 pp., with 201 illustrations. Baltimore: The Williams and Wilkins Company, 1945. \$8.50.

This book was first published in 1942 in England, where it has since enjoyed a well deserved popularity. There, as in the United States, neurosurgeons are few and far between outside the large medical centers, and the majority of head injuries are treated by general surgeons, for whom this volume is an excellent guide. Profusely and beautifully illustrated, it leaves no question of pathology, diagnosis, treatment or operative technique unanswered. Although American neurosurgeons may disagree with certain aspects of the answers, the basic principles are beyond argument. The crisp, clear text is characteristic of the best British medical writing. The book is highly recommended to students and interns as well as to all who treat head injuries.

The Art of Medicine in Relation to the Progress of Thought: A lecture in the history of science course in the University of Cambridge, February 10, 1945. By A. E. Clark-Kennedy, M.D., F.R.C.P. 12°, paper, 48 pp. Cambridge, England: University Press, 1945. 75 cents.

Clark-Kennedy, in this lecture delivered at Cambridge University, briefly reviews the evolution of medicine from Hippocrates to the present time. The Hippocratic period, from the sixth century B.C. to the death of Galen at the end of the second century B.C., was notable for three great contributions: the observation of disease as an objective phenomenon and the keeping of accurate records of cases, the development of high moral standards and the adoption of an ethical code, the Hippocratic oath, and the establishment of the idea of the physician as a necessary aid to living in human society. The Renaissance period, beginning with the publication of the anatomy of Vesalius in 1543 and ending with the publication of the first complete book on physiology of the human body by René Descartes, was notable for the work of Leonardo da Vinci, Vesalius, William Harvey, Malpighi, Descartes and Sydenham and for the advance of surgery. The third period, which comprises roughly the last hundred years and is notable for many great contributions to biology and medicine, includes Darwin's *Origin of Species*, Pasteur's disproof of the spontaneous generation of life, the discovery of the bacterial cause of many diseases, Virchow's theory of cellular pathology, Mendel's work on genetics, Lister's antiseptic and aseptic surgery, Pavlov's description of conditioned reflexes, Freud's chemotherapy, increasing knowledge of viruses and genes and the discoveries of insulin, the sulfonamides and penicillin.

Clinical Neurology. By Bernard J. Alpers, M.D., Sc.D. (med.). 4°, cloth, 797 pp., with 232 illustrations and 58 tables. Philadelphia: F. A. Davis Company, 1945. \$8.00.

The subject of neurology is fully covered in this new textbook by a qualified author that is aimed to give medical students and practitioners a full knowledge of the neurologic conditions likely to be encountered in practice. The text is clear, the material is well organized, the illustrations in general are excellent, and there is a good index. Many will miss references to the literature, but for the audience that the author had in mind, the book is a satisfactory one and

MOULTON — Allen T. Moulton, M.D., of Boston, died November 22. He was in his fifty-seventh year.

Dr. Moulton received his degree from University of Maryland School of Medicine and College of Physicians and Surgeons in 1911.

His widow survives.

PHELPS — John S. Phelps, M.D., of Lynn, died December 3. He was in his eighty-first year.

Dr. Phelps received his degree from Harvard Medical School in 1893.

A niece and two nephews survive.

ROY — Joseph N. Roy, M.D., of Webster, died March 19. He was in his seventy-fifth year.

Dr. Roy received his degree from Baltimore University School of Medicine in 1902. He was a fellow of the American Medical Association.

A HUNDRED YEARS AGO

A circular has been issued by a committee of the Berkshire Medical District, addressed to the profession of Massachusetts, in which are set forth, in plain language, the grievances of the practitioners on the west side of the mountain. They apprise all whom it may concern that an application will be made to the Legislature, the next session, praying that the Massachusetts Medical Society may be reorganized, and in default of such re-organization, that the profession in the County of Berkshire may be constituted a separate and distinct medical society. The fact is, the opinion is entertained that all the essential executive officers are invariably held by persons in Boston, or near by — and as some of the malcontents have often asserted, their portion of the members are only parts and parcels of the medical machinery to hold up one or two men before the community as those whom the multitude of doctors delight to honor. They say, too, that the old trick of serving out sop by giving the interior of the State a *vice*-president, occasionally — a post that no one covets — will no longer work. All this has frequently been sounded in the ears of the Fellows on anniversary meetings, but it produced no amelioration, and now a desperation is manifested that will certainly re-make or break the old Society. — As the Boston dentist Dr. J. F. Flagg says, everyone who has any sympathy for human suffering and all who are called upon professionally to perform painful operations must feel desirous to avail themselves of the means of diminishing or destroying that state of consciousness which recognizes all violence done to the sensitive tissues of the body, while such operations are in process. He understands, however, that the free use of the *letheon* has been ceded only to the surgeons of the Massachusetts General Hospital. In spite of Dr. J. C. Warren's admonition that the *letheon* should never be employed except under the inspection of a judicious and competent person, he asks why, if he or any other reputable practitioner wishes to avail themselves of any of the

possible effects of an article of the *materna medica*, they must purchase the right to use it and use it as a patent medicine? — A Fellow writing anonymously asks whether any patent has been obtained for the *modus operandi* of reconciling the principles and avowed objects of the Massachusetts Medical Society with the recent practice of some of its leading members. He suggests that as new patents come out for new discoveries in medicine, the country practitioners might take turns with the city practitioners in writing the puffs and paying for the patent, exercising, of course, all due meekness and quietness while the patenting business is going on. — Dr. J. D. Mansfield of South Reading says that it seems to him not only ridiculous but absolutely wrong for any physician to adopt a course of action so entirely contrary to the spirit of the rules of the Massachusetts Medical Society as that assumed by the Boston surgeons. Physicians in his vicinity, he is satisfied, will use the ether if they have occasion so to do, and if ether alone does not answer the purpose they can easily find a compound that will do as well as the *patented* vapor. — Dr. A. L. Pearson of Salem disagrees with such views. Having used the new gas successfully in three cases, he believes that Dr. Morton and Dr. Jackson, at least, are entitled to the hearty thanks of the profession for their discovery. If some hunter up of obsolete theories should prove that such a thing had before been thought of, or tried, still these gentlemen are entitled to the credit of having made it, for the first time, perfectly available to the suffering, and submitted it to the test of those competent to decide on its merits, without being content to rest its pretensions on nonprofessional credulity or popular notoriety. — Dr. Henry J. Bigelow reports that a few days since, he tied the Femoral Artery of a patient who was unable to pay for the operation. He found no difficulty in obtaining the gratuitous use of the ethereal vapor, nor could he conceive that others would in similar circumstances. — We learn that in the United States with a population of 20,000,000 of people, there are about thirty medical schools, in which there are probably an average annual number of 4500 students, 1300 of whom are yearly graduated. No wonder there is such a prodigious competition for professional existence. — It seems that the War Department may be somewhat annoyed by persons wishing employment as surgeons in the Army. What will become of all the young doctors if some outlet is not found for them? — Dr. Nathan Holmes, of St. Louis, Mo., announces that whiskey, or any other stimulus, freely given till there is a high pulse, will cure the bite of the rattlesnake. He says that he doubts whether fifty rattlesnakes could poison a man when fully drunk. — Smallpox is again creeping on toward New England. Dr. Thomas Sanborn of Newport, New Hampshire, reports ten cases in Goshen, all vaccinated several years pre-

PROBLEMS ARISING IN THE TREATMENT OF SYPHILIS WITH PENICILLIN

WILLIAM R. HILL, M.D.*

BOSTON

THIS report deals with the therapeutic pitfalls encountered in 125 patients with various types of syphilis who were treated with penicillin at the Massachusetts General Hospital subsequent to November, 1944. All these patients were hospitalized and treated for periods ranging from eight to fifteen days. Penicillin in aqueous solution was administered intramuscularly in doses of 20,000 to 40,000 Oxford units every three hours, day and night. The total dose was from a minimum of 1,200,000 to 2,400,000 Oxford units. Arsenicals and bismuth were not used concomitantly with penicillin, but in most patients with interstitial keratitis or neurosyphilis, fever therapy supplemented the treatment with penicillin.

PENICILLIN RESISTANCE

Late Syphilis

In this series the majority of patients with late syphilis who had exhibited persistently positive serologic reactions (Wassermann fastness) and who had received adequate treatment with arsenicals and bismuth before penicillin therapy was begun failed to show an appreciable reduction in the serologic titer. Occasionally, a negative serologic reaction was noted immediately following penicillin therapy. Re-examination some months later showed that the change was only temporary.

The results in the cases of acute interstitial keratitis treated with penicillin were unpredictable. Penicillin alone was administered to 3 patients in total doses of 1,200,000 to 2,400,000 Oxford units. This was combined with malaria therapy in 1 case and with typhoid vaccine to produce fever in another. Two patients who were treated with penicillin alone experienced favorable clinical results, no subjective or objective improvement was noted in the remaining 3. One patient, who improved clinically and in whom, after ten months' follow-up study, a serologic reversal was obtained, had been treated with a total dose of 1,200,000 Oxford units of penicillin alone.

Three patients who had advanced optic atrophy — 1 with congenital, and the other 2 with acquired syphilis — failed to respond clinically to a total dose of 2,400,000 Oxford units, which each received over a period of eight days. No improvement in the visual fields had been noted six months after therapy had ended. One patient with deafness due to involvement of the eighth cranial nerve was treated with 1,200,000 Oxford units but did not respond favorably.

None of the 5 patients with neurosyphilis with lightning pains showed any change in the character or intensity of the pains following treatment with a total dose of 2,400,000 Oxford units of penicillin. One patient who had neurosyphilis and gastric crises did not benefit when a total dose of 900,000 Oxford units was given intrathecally, together with 2,400,000 Oxford units by the intramuscular route.

O'Leary, Brunsting and Ockuly¹ reported no improvement in gastric crises, ataxia or incontinence in persons with neurosyphilis, nor was clinical improvement noted in their cases of early dementia paralytica in which penicillin alone was given.

Favorable results have been reported in late cutaneous syphilis.² Recently, however, I have had the opportunity of examining a patient with an extensive destructive gumma involving the center of the face, including the nasal septum, and hard palate who had received 2,400,000 Oxford units of penicillin before admission, without improvement. Therapy with induced malaria completely resolved the lesion.

Early Syphilis

We have noted no evidence of penicillin resistance in this type of case. Tyson,³ however, reported the case of a colored man who had primary syphilis. The dark-field examination was positive. He was treated with a total dose of 2,400,000 Oxford units of penicillin intramuscularly in the course of four days. The penile lesion did not heal. *Treponema pallidum* was seen on dark-field examination of the lesion four months later. At that time, also, lesions of secondary syphilis were present and a

*Assistant in medicine and in dermatology, Harvard Medical School; assistant physician and assistant in dermatology in charge of the South Medical Clinic (Syphilis), Massachusetts General Hospital.

unusually free from errors. It is not an unusual book but rather a standard text, similar to many that have been published in the past. The author has shown excellent discrimination in selecting the illustrations and in making the text readable. The book, however, is not distinguished in the sense that it presents a new point of view, its value lies in the careful methods used to analyze the principles of neurologic syndromes, particularly as they appear in the more frequent pathologic conditions.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Pathology of Tropical Diseases. An atlas. By J. E. Ash, M.D., director, Army Institute of Pathology, Army Medical Museum, and Sophie Spitz, M.D., pathologist, Army Institute of Pathology, Army Medical Museum. 4°, cloth, 350 pp., with 941 illustrations. Philadelphia: W. B. Saunders Company, 1945. \$8.00.

This new atlas has been written to fill a gap in the literature of tropical diseases. An introductory text precedes each series of illustrations. Emphasis has been placed on diseases that have proved to be of greatest significance from a military standpoint and that are likely to be of importance to the civilian profession. Illustrations are based on the collections of the Army Institute of Pathology in the Army Medical Museum, with additional material from civilian sources. This work should prove valuable as a reference source in its particular field.

A Manual of Surgical Anatomy. Prepared under the auspices of the Committee on Surgery, Division of Medical Sciences, National Research Council. By Tom Jones and W. C. Shepard. 12°, cloth, 254 pp., illustrated. Philadelphia and London: W. B. Saunders Company, 1945. \$5.00.

This manual of surgical anatomy completes the series of military surgical manuals edited by the Committee on Surgery of the National Research Council and primarily intended for the use of medical officers of the United States Army and Navy. The volume consists of one hundred and thirty-nine pages of illustrations and one hundred and fifteen pages of an explanatory index. This small manual should prove valuable to medical students and civilian surgeons for ready reference purposes.

Doctors at War. Edited by Morris Fishbein, M.D., chairman of the Committee on Information, Division of Medical Sciences, National Research Council. 8°, cloth, 418 pp., with 82 illustrations. New York: E. P. Dutton and Company, Incorporated, 1945. \$5.00.

This collective work makes available the personal accounts of many of the medical leaders who directed the work of vital military and civilian agencies during the war years. The whole field of military medicine is covered from Selective Service to rehabilitation centers. Chapters are also included on the medical activities of the Veterans Administration, the American Red Cross and the National Research Council during World War II. This book, written by sixteen leading authorities responsible for organizing medical welfare, is intended for the layman as well as the doctor and should be in all public and medical libraries and should prove interesting to all physicians. The text is excellently edited by Dr. Fishbein and is well printed with a good type on good paper.

A Textbook of Neuro-Anatomy. By Albert Kuntz, Ph.D., M.D., professor of microanatomy, St. Louis University School of Medicine. Fourth edition, thoroughly revised. 8°, cloth, 478 pp., with 325 illustrations. Philadelphia: Lea and Febiger, 1945. \$6.50.

This third edition of a standard reference work has been thoroughly revised and enlarged in the light of new knowledge gained through the efforts of many investigators working during the period since the publication of the second edition. The

text has been in part reorganized and rewritten, and an attempt has been made to incorporate the essential findings recorded in the recent literature. This text should be in the libraries of all neurologists and medical reference collections.

Howell's Textbook of Physiology. Edited by John F. Fulton, M.D., Sterling Professor of Physiology, Yale University School of Medicine. Fifteenth edition. 8°, cloth, 1304 pp., with 507 illustrations. London: W. B. Saunders Company, 1946. \$8.00.

This fifteenth edition of Howell's textbook should be considered a new textbook of physiology, since it is the joint work of twenty-four contributors, edited by Dr. Fulton, the first fourteen editions were written solely by Dr. Howell. The various contributors, all authorities in their particular field, have brought their subjects up to date, including the knowledge gained during World War II. Many new chapters have been added, and many others have been rewritten in their entirety. This new text should prove of value as a standard reference work.

The Autonomic Nervous System. By Albert Kuntz, Ph.D., M.D., professor of microanatomy, St. Louis University School of Medicine. Third edition, enlarged and thoroughly revised. 8°, cloth, 687 pp., with 91 illustrations. Philadelphia: Lea and Febiger, 1945. \$8.50.

This fourth edition of an authoritative text has been thoroughly revised and in part rewritten. The text has not been materially extended, although new material has been incorporated, including more complete and accurate accounts of the anatomic and functional relations of the diencephalon and the corpus striatum and the conduction pathways for visceral impulses. Also, new data concerning cortical projection areas, the connections of subcortical centers with the cerebral cortex and the relation of these centers in the extrapyramidal projection system, the arrangement of the cortical neuron, the synaptic connections of afferent fibers within the cortex and the functional relation of cortical neurons with one another are included. The book is well printed on good paper with a good type and should be in the reference collections of all neurologists and medical libraries.

A Textbook of Surgery. By American authors. Edited by Frederick Christopher, M.D., associate professor of surgery, Northwestern University Medical School, and chief surgeon, Evanston (Illinois) Hospital. Fourth edition, revised and reset. 4°, cloth, 1548 pp., with 1483 illustrations on 762 figures. Philadelphia and London: W. B. Saunders Company, 1945. \$10.00.

This fourth edition of a standard authoritative composite text on surgery, first published in 1936, has been thoroughly revised and reset. Two important new sections have been added, one on military surgery and the other on chemotherapy and surgical infection, including the use of penicillin and the sulfonamides. Other entirely new sections include actinomycosis, burns, shock, indolent ulcers, vascular-tissue tumors, tumors of the sympathetic nervous system, fractures of the radius and ulna, tumors of the breast, inflammations of the chest wall, wounds of the thorax, pilonidal sinuses and cysts, the peritoneum, diverticulitis and ulcerative colitis, unusual hernias, diverticula of the urinary bladder, diseases of the vulva and vaginal fistula. This work should prove valuable as a reference source to all physicians and surgeons and should be in all medical libraries.

Principles of Dynamic Psychiatry, including an Integrative Approach to Abnormal and Clinical Psychology. By Jules H. Masserman, M.D., Division of Psychiatry, Department of Medicine, University of Chicago. 8°, cloth, 322 pp., with 4 plates. Philadelphia and London: W. B. Saunders Company, 1946. \$4.00.

The purposes of this work are to provide an orientative introduction to the principles of modern dynamic psychiatry, to outline the applications to the techniques of clinical diagnosis and to demonstrate the rationale and methods of effective therapy.

(Notices on page xvi)

of the disease by penicillin but became reinfected after his wife developed the lesion

In both relapse in early syphilis and reinfection, retreatment should consist of double the previous dose or more, with the addition of arsenic and bismuth. For data on this phase, reference to a report of the Committee on Medical Research and the United States Public Health Service¹² is advised. The decision to retreat usually arises between the third and the twelfth month following the original therapy.

REACTIONS

Although the incidence of severe reactions is insignificant when compared with those attending routine treatment with arsenic and bismuth, reactions do occur among patients treated with penicillin.

Shocklike Reactions

The Herxheimer reaction was noted in 75 per cent of patients with early syphilis in this series. In such cases, within the first eight hours and most frequently after the second injection, a rise in temperature to from 100 to 103°F occurs. The patient complains of chilliness, headache, backache and malaise. There may be an exacerbation of pre-existing lesions. This does not call for discontinuation of therapy. The patient becomes symptom free in another twelve hours. According to Stokes, Beerman and Ingraham,¹³ this reaction occurs in 20 per cent of patients with late syphilis who are treated with penicillin. It may be grave, as is evidenced in the report of Lentz and his group,¹⁴ who observed threatened abortion in 2 pregnant women treated for early syphilis with penicillin. This occurred within eighteen hours after the beginning of treatment in one case and within forty-eight hours in the other. The drug was discontinued immediately but was resumed in full dosage in twenty-four hours, without recurrence. Lentz et al believe that this type of Herxheimer reaction may be referred to as "placental shock." In another article, Ingraham and his associates⁵ report that a patient with early latent syphilis in the fourth month of pregnancy aborted on the fourth day after the beginning of penicillin therapy. In this case, treatment was begun cautiously, with a low dosage of penicillin for the first three days. Goodwin and Moore¹⁵ do not agree that the reaction was due to penicillin.

Leavitt¹⁶ noted that of 21 pregnant patients treated with penicillin, 8 manifested symptoms of uterine activity, consisting of uterine cramps or bleeding, or both. In 2 cases, evacuation of the contents of the uterus occurred. In Beerman and Ingraham's⁴ series, a patient had a miscarriage during the course of treatment, and in another case, it was necessary to stop treatment until the symptoms of threatened miscarriage had subsided some weeks later.

One infant with congenital syphilis suddenly experienced severe, nearly fatal collapse forty-eight hours after treatment had been begun.¹⁰ Three infants died during or soon after treatment (twenty-four hours, seven days and nine days, respectively). All the infants were under two months of age and were in poor general condition. Two other infants died (five weeks and fourteen weeks, respectively) after penicillin therapy. Whether these deaths were due to penicillin, directly or indirectly, is not known. It is prudent, in the penicillin treatment of debilitated children, to employ considerable caution.¹⁷

The 2 cases of cardiovascular syphilis reported by Dolkart and Schweimlein¹⁸ in which anigal symptoms appeared shortly after the beginning of penicillin therapy are examples of a therapeutic paradox—a shocklike reaction that occurs at times in other vital structures, such as the liver. In all cases in which the possibility of therapeutic shock may be anticipated, it is wise to reduce the penicillin dosage by three fourths to a half for the first forty-eight hours. This reduction may be compensated for by prolongation of the course of treatment. In the present series, untoward reactions were not observed in a patient treated with penicillin who had syphilis and hypertensive cardiovascular disease and who was decompensated, or in a person who had cardiovascular syphilis with aortic regurgitation.

Neymann and his co-workers¹⁹ reported 2 fatal cases following the use of penicillin intrathecally. They stated that the route is dangerous if more than 30,000 units are injected and that the daily injection of this dose prolonged for more than five days is hazardous. Their patients who died following such treatment exhibited tenseness at first. This was followed by generalized muscular twitching and finally by severe convulsions.

In this series a patient developed postarsenical jaundice, from which he appeared to make an uneventful recovery. Three months later he returned to the hospital for study and was given 2,400,000 Oxford units of penicillin over a period of eight days. Soon, the jaundice reappeared. This was followed by a progressively fatal course. A post-mortem diagnosis of subacute yellow atrophy was made. The question whether the penicillin was responsible for death cannot be answered satisfactorily. In the presence of previous liver damage, however, penicillin should be employed cautiously if at all.

Sensitization Reactions

Only 2 patients in this series developed urticaria while undergoing penicillin therapy for syphilis. But according to Anderson,²⁰ from 2 to 5 per cent of patients treated with penicillin develop urticaria. This may appear on the first day of treatment or may not become apparent until several days after treatment has been completed. It usually develops during the second week. Occasionally, it is severe,

serologic test was reported as positive. Retreatment consisted of 600,000 Oxford units of penicillin, in addition to eight hours of fever therapy, this caused resolution of the lesions. Three months later, the serologic tests were reported negative. The lesson to be learned is that the time element (in this case, four days) is more important in cure than the total dose. The duration of penicillin therapy (four days) also appears to have been significant in Beerman and Ingraham's case⁴ in which treatment failed. In both cases the time was too short to sustain a therapeutic blood level of the drug.

LIMITATIONS OF THERAPY

Relapse

The effectiveness of a new antispirethetal agent in early syphilis is judged by the incidence of relapse, both clinical and serologic, following its use. Relapse has been defined as either a persistent, rising serologic titer or clinical evidence of progression of the disease. Its implications regarding public health are obvious.

Among 75 patients with early syphilis treated at the Massachusetts General Hospital, 2 had serologic and 3 had clinical (mucocutaneous) relapses — a rate of approximately 7 per cent in patients followed for at least six months. One of the latter group, a woman five months' pregnant with secondary syphilis, had been treated with 1,200,000 Oxford units of penicillin. At the time of delivery of a full-term, normal-appearing infant, the mother's serologic reaction was positive although tending toward negativity. The serologic reaction in the infant was negative until the third month, when it became positive. At that time, both the mother and the infant presented cutaneous lesions suggestive of secondary syphilis. From the perianal lesion of the infant, material taken for a dark-field examination revealed *Tr pallidum*. Progress after treatment with double the total dose for the mother — 2,400,000 Oxford units of penicillin — and a total dose of 1,200,000 units for the infant has been satisfactory. Beerman and Ingraham⁴ reported a somewhat similar case in which the same dose was given in four days. This patient, who had not been cured of syphilis, had an infectious relapse and transmitted the disease to the infant about the time of delivery.

In a group of 27 pregnant women with early syphilis who were treated with penicillin by Ingraham and his co-workers,⁵ the rate of clinical and serologic relapse was 11 per cent.

Moore⁶ reported that the incidence of relapse when penicillin was administered alone was in direct relation to the total dose given by the intramuscular route in a period of seven and a half days. It was greatest with 60,000 units and least with 1,200,000. Relapse appeared to be more frequent after intravenous use than after intramuscular administration of comparable doses.

In a report by the Committee on Medical Research and the United States Public Health Service⁷ on the treatment of early syphilis with penicillin, the lowest cumulative failure rate — 15 per cent at the end of eleven months' follow-up study — occurred following the administration of a total dose of 2,400,000 Oxford units. With a total dose of 60,000 units, the rate was 62 per cent.

In a series of cases of early syphilis reported by Moore et al.,⁸ patients with seronegative primary syphilis treated with intramuscular penicillin showed a relapse rate of 3.2 per cent. The rate was 5.0 per cent in those with seropositive primary syphilis, and 9.8 per cent in those with secondary syphilis. Leifer⁹ reported that 96 patients with early syphilis treated with a total of 1,200,000 Oxford units had a relapse rate of 9.6 per cent. Leifer's series also included 2 patients who had neurologic relapses. Although the seriousness of this complication was appreciated, it was not encountered in the series at the Massachusetts General Hospital.

The lowest incidence of relapse⁸ and the most favorable serologic response was seen in a small group of patients treated with 60,000 and 300,000 Oxford units of penicillin, together with a known subcurative dose of Mapharsen. Similar results have been reported in patients treated with penicillin and bismuth.⁷

Observation of 69 infants treated for infantile congenital syphilis revealed serologic relapse in 5 patients, with clinical relapse in 2 of these cases.¹⁰ Serologic relapse occurred in three to six months after treatment, and clinical relapse at six months.

Serologic and clinical relapse in the cases of early syphilis in this series was noted between the third and the ninth month, but the danger period extended to the end of the second year following the original treatment.

Reinfection

Reinfection as opposed to relapse is infrequent. Of 150 supposed reinfections, clinicians associated with the Central Statistical Unit agreed to fulfillment of adequate criteria of reinfection in only 2 cases.⁷

Although one case failed to fulfill these rigid criteria, it portrayed a frequent pitfall referred to as "pingpong syphilis" (Schoch and Alexander¹¹), which occurs uniquely in penicillin-treated syphilis. A male patient was discovered to have a dark-field-positive chancre, for which he was given 2,400,000 Oxford units of penicillin intramuscularly. A month later, his wife developed a vulvar lesion. Her serologic reaction at that time was positive, but no dark-field examination was performed. Early in the next month she received 2,400,000 Oxford units of penicillin intramuscularly. Three weeks later the husband noted a penile lesion on the opposite side from the original chancre. Dark-field examination was negative at that time but was reported positive for *Tr pallidum* a month later. It is reasonable to believe that the husband after infecting his wife was cured.

this treatment can be obtained. They are instructed to present their separation-report leaflet to the physician of their choice, informing him that the type, amount and dates of treatment are on file at the state health department. This leaflet shows the results of serologic tests, including a report of the examination of the cerebrospinal fluid taken before discharge from the service. The treatment these patients have had is listed on Form 78A. If for some reason this form is not obtainable from the state health department, or if further information is desired, the physician can write to the Bureau of Medicine and Surgery, United States Navy, or to the Preventive Medical Service, Office of the Surgeon General, United States Army, in Washington. With this information at hand, the attending physician should be able to reach some decision on future follow-up study of the patient.

At the Massachusetts General Hospital, patients with early syphilis who have been treated with penicillin are seen for follow-up examinations (including at each visit a complete physical examination, with special attention to the skin and mucous membranes, and a quantitative serologic test) every two weeks for the first year. At the end of the first year, if there has been no clinical relapse and serologic tests are negative, another examination of the cerebrospinal fluid should be made. During the second year, the patient should be seen at least every three months. Attention is again called to clinical and serologic relapse, which is most frequent in the first two years after the initial treatment for early syphilis. At the end of the second year, assuming that all findings are negative, the patient is placed on a yearly follow-up basis for the remainder of his life, the wisdom of programs that advocate following the treated veteran for a maximum of only five years is doubtful. Again, assuming that the patient is progressing satisfactorily, an examination of the cardiovascular system, including roentgenology and fluoroscopy, is made five years after treatment has been completed. This entire subject, together with the action taken on it by the armed forces and civilian public-health authorities and with the part the civilian physician and the veteran himself play in it, has been reviewed in detail by Perkins.²⁴

It is further realized that men and women returning from the service have a responsibility in this program that they may, for various reasons, choose to neglect. Although proper methods of handling this situation exist in the state and local departments of public health, the private physician is lost when the patient fails in his duty. In certain states and communities, however, the private physician can, by communicating with the department of public health, by telephone or in writing, obtain the services of a trained social worker in venereal disease, who will get in touch with the lapsing patient. In this

capacity, the social worker acts as the private physician's confidential representative, urging the patient to continue under the care of his physician. Persons failing to respond to this approach should be reported to the proper state or local public-health department for more aggressive action.

Marriage

When should a person who has had early syphilis and who has been treated with penicillin marry? My policy has been to advise postponing marriage until two years after the blood serologic reaction had become negative, provided that during this interval the patient is free from clinical manifestations and exhibits a persistently negative serologic reaction. At the end of this probationary period a spinal-fluid test must also be negative. Anything short of this regime invites disaster.

SUMMARY

Although many of the untoward results of penicillin therapy will be remedied as experience with penicillin increases, especially when more studies become available in which various combinations of other antisyphilitic drugs are used in conjunction with penicillin, therapeutic overenthusiasm on the part of the practicing physician must be tempered by the facts presented above.

It is the duty of the physician who treats syphilis to know the types of the disease in which results with penicillin are inconclusive, to understand such therapeutic pitfalls as lapse, relapse, resistance, reinfection and the problems of retreatment and to familiarize himself with reaction hazards. It is incumbent on him to protect the public health by encouraging the returning veteran to continue the splendid work that the armed forces have performed in the treatment of early syphilis and by advising against the ill timed marriage of patients who have been treated for early syphilis with penicillin. Finally, a high index of suspicion regarding syphilis will protect the practicing physician from unwittingly adding to the reservoir of hidden syphilis by administering treatment that may mask the disease.

but in most cases it is mild and frequently disappears even if treatment is continued.

Another type of allergic response is a vesiculobullous or papular eruption, generally followed by desquamation. This also occurs in the first twenty-four hours. The continuation of therapy in these cases aggravates the disease.

Transient gastrointestinal reactions, consisting of nausea, vomiting and diarrhea, have been noted in syphilitic patients treated with penicillin.

The maximal dose of penicillin that can safely be given to man has not been determined. So far as is known, penicillin is not incompatible with any other antisyphilitic drug.

PUBLIC-HEALTH ASPECTS

Masking of Syphilis

In 1 case in this series the treatment of gonorrhea with penicillin during the incubation period of syphilis masked the disease. The diagnosis of syphilis was delayed for six months, and during the interval the patient infected his wife. Walker and Barton²¹ reviewed 8 cases in which patients with gonorrhea were treated with 100,000 Oxford units of penicillin—given in one day—during the incubation period of syphilis. Such a small dose of penicillin, although capable of curing the gonorrhea, is likely to suppress the primary and secondary manifestations of a concomitant early syphilitic infection but does not prevent recurrences. Under these circumstances, the patient is denied the benefit of adequate treatment for syphilis in the seronegative stage, in which the chances of cure are greatest, and the public is exposed to a definite source of infection. In most cases the patient's condition is diagnosed weeks or months later when he is seen with a clinical or serologic relapse.

Magnuson and Eagle²² stated that, with the increasing use of penicillin for gonorrhea, it is probable that the number of aborted, delayed or symptomatically acquired lesions of early syphilis will increase. MacKenzie and Wrong²³ therefore advise the use of sulfonamides rather than penicillin in cases of urethritis in which a coincidental infection with syphilis is suspected. These authors noted that penicillin administered during the incubation period of syphilis in subcurative doses modified the early bacteriologic and serologic findings. In their cases the appearance of the chancre was delayed to from sixty to seventy days, rather than the usual twenty-six days, and the serologic reaction became positive in four to five months, instead of an average of forty-five days, from the date of the infection. They also found that when the primary lesion of syphilis appeared, it was necessary to perform repeated dark-field examinations before a positive result was obtained. Therefore, it seems necessary to subject patients receiving penicillin for gonorrhea to a six months' follow-up study for syphilis. Any patient who has gonorrhea and shows an early Herxheimer

reaction,²¹ evidenced by a rise in temperature after the first injection of penicillin, should be examined for syphilis.

Another pernicious habit concerns the blanket use of penicillin in mucocutaneous ulcerations, in which such treatment may mask the coincidental development of syphilis. A patient in this series had been treated for an ulcerative genital lesion by a physician with 600,000 Oxford units of penicillin, peanut oil and beeswax mixture intramuscularly, with no attempt to diagnose the condition by dark-field examination or pretreatment serologic reaction. This treatment, which was inadequate for early syphilis, was sufficient to render the dark-field examination negative for *Tr pallidum* and probably delayed the development of a positive serologic reaction. To protect such patients and the community at large, it is necessary to accept the diagnosis of syphilis under these conditions and to offer treatment sufficient to cure.

Another case was that of a young woman with an ulceration of the lower lip who had been treated with penicillin troches. The medication caused the lesions to regress temporarily, but several weeks later, when the diagnosis was suspected, a dark-field examination revealed *Tr pallidum*. A serologic test taken at that time was positive.

Lapse of Treatment

In general, experience with this group of patients revealed that case holding is far more difficult for penicillin-treated early syphilis than for patients treated under the arsenic and bismuth regime. Under the latter, the patient is satisfied that something positive is being done at each visit—namely, treatment. On follow-up study after penicillin treatment he is merely "looked at" and blood is drawn for a serologic test. This circumstance, together with the early favorable reports of the test, lulls him into complacency. One of the great advantages of the arsenic and bismuth regime, from a public-health viewpoint, was that patients with early syphilis received some treatment continuously during the first year and a half or two years of the disease, the time of greatest relapse.

The Returning Veteran

High on the list of problems in public health in the treatment of syphilis with penicillin will be the follow-up and case-holding system for the returning members of the armed forces who have been treated for syphilis with penicillin while in the service. The family physician will undoubtedly share in this aspect of the problem. He should therefore be acquainted with the following facts, if his patient and the community are to be protected.

All service personnel who have been treated for syphilis while members of the armed forces are informed before discharge what is expected of them in following up their treatment and are told where

considered from an economic rather than a medical standpoint

Another aspect of medical care is that of public health and preventive medicine. Half the counties in the United States do not have a full time public-health service. In other sections the department of public health is under political control, and there is no efficiency of administration. It would not be feasible, of course, for every county in the United States to have a full-time public-health department. Indeed, there are five counties in the United States with only five persons per square mile, they could not afford it and would not need it. But neighboring counties could join and form a district health department, with a traveling health service. This could be done in most states within their own economy. If state funds are lacking, there is a legitimate opportunity for the federal government to help, leaving the control of the situation in local hands.

It is much better to prevent disease than to cure it after it has started, and the control of many diseases is dependent on the quality of public-health facilities, of sewage and mosquito control and of water and milk supplies. Some of the diseases can be entirely eliminated by proper public-health measures. Again, there is no necessity for pouring in medical care.

The shortage of physicians in certain areas is widely discussed. The doctor does not settle in a certain community primarily because there are not facilities for him to bring up his family and educate his children, or for competent practice. He has been trained to practice a high type of medicine, and when he goes to a community and finds no adequate facilities he either leaves or remains and practices poor medicine, which is even worse. The solution is the provision of hospital and diagnostic facilities in these areas. That approach is the main substance of the Hill-Burton Bill in Congress — providing such facilities throughout the country where they are not now available, the states retaining control over these institutions constructed with federal money. In some areas the lack of medical care will thereby, to a certain extent, be solved, in others it may be necessary to provide a subsidy for a physician to go to an area because of the small number of patients to be cared for. This problem can be solved through voluntary agencies.

Medical care has become more expensive, I believe, primarily because of the increased science that has developed. Seventy-five years ago, medicine was not a science but an art, it is now an art, as well as a science. There are those who wish to throw the art out the window and make medicine 100 per cent science, but the result would not be satisfactory. There is still the individual touch in medicine, as well as the effect. You men know, as well as anybody in the world, that the treatment in two cases of pneumonia cannot be identical merely

because the diagnosis is the same. Psychology is involved in the treatment of every patient — in the so-called "doctor-patient relation," which is one of the reasons for the success of the American system of medicine, preventing the doctor from being exclusively scientific and the patient from being merely a case number.

The increased expense is not so much in the care that the physician gives — he is paid little more than he was a generation ago for a house call or an office visit, the cost is in diagnosis. The doctor must have expensive pieces of apparatus, as well as complicated procedures, to practice competent medicine today. He must have equipment for x-ray films, electrocardiograms, blood chemical studies and so forth, all of which cost the patient money. It is those matters that need attention and whose solution will be aided by some such means as the Hill-Burton Bill.

One other important measure is in insurance, about which a good deal is heard at present. You are all familiar with the proposal now before Congress, with hearings before the Senate Subcommittee on Education and Labor, the Wagner-Murray-Dingell Bill calling for compulsory health insurance. Organized medicine has sponsored a voluntary program. Certain members of the committee, Senators Murray, Wagner and Pepper, assert that the voluntary system will not work. They cite reasons, every one of which is susceptible of overturn. America is undoubtedly the best insured nation in the world, from every aspect. The American people are insurance minded, but they must be sold on the idea of insuring their health. I understand that it took fifty years to make the idea of life insurance successful. I do not mean to intimate that it will take fifty years for voluntary health insurance to succeed. In those days, nobody knew anything about the types of insurance that could be obtained. At present, it should be comparatively simple to sell health insurance, but it must be made available.

There are two types of hospital insurance — that provided by the Blue Cross and that sold by various commercial companies. The Blue Cross alone has somewhere around 22,000,000 people insured, and the number is going up week by week, in fact, every time I speak on the subject I have to amend the figures, so that I am not sure that 22,000,000 is correct at the present time. And there are many more who are insured for hospitalization through insurance companies.

Then, too, people are carrying all sorts of health and accident insurance. Probably 30,000,000 in the United States have some form of protection against illness. Not all of it is the same. Some of it is complete, and some of it covers emergencies; some of it covers surgery and obstetrics, and some of it covers hospital and medical care, some of it is commercial insurance, some of it is industrial insurance,

THE MEDICAL-CARE PROBLEM IN THE UNITED STATES*

LOUIS H. BAUER, M.D.†

HEMPSTEAD, NEW YORK

I SUPPOSE that there is no problem quite so controversial in the United States as that of medical care. We hear a great deal of propaganda—in its modern connotation, not its original one. It is not information, it is information on one side, an attempt to sway people into changing their opinions, regardless of facts. The medical profession and the whole subject of medical care have been the object of considerable vicious propaganda of that order for the last several years.

It is quite true that medical care in many areas of the United States is not what it should be, and that it is susceptible of a great deal of improvement. Many things that are said about it, however, are definitely not true. Of course, those things are said with the idea of deluding the public, so that they will accept something quite foreign to the American idea of how things should be done.

One of the subjects most frequently discussed is the matter of Selective Service statistics. It is constantly stated that these statistics showed that American manhood is falling apart. The facts are that although 4,217,000 men were rejected, 582,000 of those were rejected for mental deficiency, including 250,000 illiterates, and about 701,000 for neuropsychiatric defects. The psychiatrists would be the first to admit that those men could not have been made fit for medical service, no matter how much medical care they received. Furthermore, out of the total number, there were those who were totally blind or totally deaf, as well as those without an arm or a leg.

Therefore, when the statistics are analyzed down to the last man, it is found that not over 15 to 20 per cent, and probably not even that number, could have been salvaged for the armed forces with any

medical care. Most of those rejected who were given an opportunity to have the defects corrected refused. Furthermore, people fail to consider that the medical standards of the United States Army and Navy were the highest in the world. Men rejected by our forces crossed the line into Canada and were accepted. No one would say that the cadets at West Point and Annapolis were in poor physical shape. Yet the fact remains that not more than 40 or 50 per cent pass the physical examination for flying.

Many other charges are made that do not concern medical problems at all. For example, as I have pointed out before, there was a cartoon several years ago showing a woman in rags and a sad state of malnutrition, surrounded by children in a similar condition, and the cartoon was entitled, "These people need medical care." That was used as propaganda to overturn our system of medical care in the United States. The people portrayed needed a great many other things worse. If they had been properly clothed and housed and fed, they probably would have needed little medical care. The problem is really economic, it becomes medical because of the economic factors, and all the medical care in the world will not solve the problem. The cure of the evil is an economic one, which is the community's responsibility and not primarily that of the medical profession.

One of the points of the American Medical Association program is that people should have proper housing, clothing and food, and that they should obtain these on an individual basis whenever possible, when it is not possible—for example, if they are misfits in the community—the community must take care of them, and so on up to higher levels if the local resources are inadequate. Thus, again, a certain section of the population that is in need of medical care is eliminated if the problem is

*Presented at the annual meeting of the New Hampshire Medical Society, Manchester, May 14, 1946.

†Member, Board of Trustees, American Medical Association.

Even Mr. Altmeyer, in his cross-examination, had to admit that the choice was limited. He also said that if the physicians in a community did not agree to serve under the plan, the Public Health Service would send doctors into the area to practice medicine. That is how much the free choice amounts to.

The statement is also made that organized medicine is unfair when it claims that this is the first step in national socialization. A glance at the background is sufficient. What happened in Germany? The Germans had compulsory sickness insurance. What is happening in England? They are socializing all their public utilities, even the Bank of England. In 1938 or 1939, the year that the American Medical Association met in Atlantic City, a senator from Illinois came directly from Washington and asked permission to speak to the House of Delegates. That was granted. He made the following statement:

We know nothing of patient, don't recognize its existence. It is your creation. We recognize an instrument called citizen, who is essential to the welfare of government.

Most of us were brought up to believe that the state was for the welfare of the citizen. One can find similar words about the citizen and the state in *Mein Kampf*, and yet the senator's statement has never been denied by anybody in Washington.

There are other shortcomings in the Bill. Compulsory insurance will be extremely expensive, the medicine provided will be anything but free. This Bill does not mention how the money is to be raised. That, of course, was done for a specific purpose to get the bill into the hands of Senator Murray's committee. If taxes were mentioned, it would have to go to the Finance Committee, of which Senator George is chairman, where it probably would have received a frosty reception.

The money will have to be raised somehow. President Truman mentioned a 4 per cent tax, up to \$3600, for each employed member of the family. If two people in the family received \$3600, they would have to pay \$288 for medical care. That is an extreme case, it may be said, because many people are in the lower income brackets. But that is not necessarily making the outlay of a family smaller, because when there are more people in the same family working, then the net cost will be higher. It is estimated that approximately four billion dollars, which is stated to be the present cost of medical care in the United States, can be raised by taxes. In my opinion, fourteen billion dollars would probably come nearer the actual figure if such a vicious scheme as this were adopted. We do not know how many bureaucrats would be given jobs if the bill went into effect, but at least 300,000 to 400,000 would undoubtedly be employed. In England, they have two nonmedical employees to one physician, and, in the extravagant way we do things in this country, there would probably be three or four to one. That army of people would

have to be taken care of before any poor patient got a doctor. Inspections would be necessary everywhere. A bureaucratic government cannot be run without red tape — it thrives on it. The experiences of the depression should be remembered. In New York the Emergency Relief Administration prescribed regulations whereby doctors had to ask permission to visit a patient. They could go and make an initial call, and whether they got paid for it or not, they had to estimate the number of calls necessary for them to make on that patient, as well as giving the diagnosis on the patient, all the information being submitted on a postal card, mind you. If they found that the patient had complications, they had to get extra permission for three or four more calls. They were also told what to prescribe and what not to prescribe. Certain things were too expensive, and the government clerk was the one to prescribe, not the doctor. All these up-lifters say that no interference in the practice of medicine is intended in the bill. Why was there interference by the Emergency Relief Administration during the depression? We can expect nothing different. It will be the same thing, only more so. It is simply the initial attempt on the part of a certain group to make this a totally socialist government. The next step will be easy.

There are one or two other matters in this bill that I should like to mention. A so-called "advisory council" is emphasized as being quite important. It will have sixteen members, I believe, who are to be appointed by the Surgeon-General of the Public Health Service. These names must be selected from panels submitted by professional and other societies. But the board has no authority. It is advisory only. Furthermore, do you think for one minute that the Surgeon-General will appoint to the board people he knows are going to disagree with him? Of course not! That board will be a sounding board, that is the only relation that it will have to a "board," in my opinion. Local boards in the various states and communities will actually run the practice of medicine.

It is all very well to say that this is not socialized medicine, that the patient will have free choice and that people will get medical care that was not previously available. It is socialized medicine. Some people may get medical care that they have never had before, but it will be inferior. In all countries where the government has taken control over the practice of medicine, the medical care has deteriorated.

Senator Pepper said that he wished the people would get as stirred up about the 600,000,000 man-hours lost from ill health as it did about the hours lost by strikes. It might be well to consider what has happened in other countries in that regard.

When compulsory insurance was developed in England, it was expected that the sickness rate would go up initially, because people would go to

and some of it is carried in the plans sponsored by the medical societies. It is interesting to note that there is an increase of 114 per cent in the number of people insured under the last system alone, which shows that this idea is growing. It has been slow, of course. And that is one thing that must be admitted when the voluntary program is attacked. But I think that it is wise to go slow.

The American Medical Association was roundly censured in many quarters when the first approval was given to voluntary medical insurance because many people believed that the American Medical Association should advance an overall plan covering everybody in the United States. Nobody knew what was wanted. There was no actuarial background. No one knew how the medical profession or the public would react. Consequently, if a plan were developed and sold over the United States, the thing would have been killed years ago, it could not have worked. Accordingly, it was considered better to experiment and to start in small areas, accepting what was good and rejecting what was bad. There has been experimentation over a period of years, and we are beginning to know what is acceptable and what is not acceptable. As a result, order is beginning to come out of chaos, and, as you probably know, the American Medical Association has just established a Division of Prepayment Medical Care and Insurance in the Council on Medical Service at headquarters in Chicago, and there has been formed an independent organization, Associated Medical Care Plans, which takes in all the plans that sell insurance, provided that they meet certain specifications set up by the Council. The idea is to make these plans uniform, so far as possible, and to have reciprocity among them so that a person moving from one state to another will not lose his insurance but may transfer to the plan in another state. Organizations having a national payroll with employees in New Hampshire, Massachusetts, New York, Pennsylvania and other places do not have to go to half a dozen different places to insure employees. They can go to one central agency, where they may be insured in different organizations. General Motors Corporation, for example, is not willing to insure its employees in New Hampshire for medical care if it cannot do the same thing for its employees in another state. It is essential that these plans be available nationally, and some arrangement should be made whereby they can be sold nationally, even though they are actually sold by different companies.

Another criticism leveled at voluntary health insurance is that few of these plans give complete medical care. That is true. The reason is that most of the plans that started out with complete coverage were unsuccessful because the public was not interested in an illness of three, four or five days, they are interested in the expensive type of illness and hospitalization, such as operation or

delivery. That type of insurance is incorporated in most of the plans, and many of them are adding medical care in the hospital—that is, the patients are protected for surgery, obstetrics, and if they have an illness that requires hospitalization they are protected for the medical care while in the hospital. It has been interesting, in New York, at least, to note that the people who have been carrying limited insurance say that this increased policy for medical care in the hospital can be sold to holders of surgical and obstetric insurance much more easily than to people with no insurance at all. In other words, the former have become more insurance minded. They see the benefits and want to extend them. The policy that will ultimately be more or less universally sold will probably cover surgery, obstetrics and medical care in the hospital. Eventually, complete medical care in the office and the home may be included, but that will take time. That is the least important, because the greatest part of the problem will have been solved if the economic situation is improved, if diseases are controlled and eliminated by proper preventive medicine and public facilities, adequate diagnostic aid and hospital facilities and if protection against the costs of surgery, obstetrics and hospital medical care is provided.

The Wagner-Murray-Dingell Bill proposes a system of national health insurance, and we are told that this is not socialized medicine. In fact, I believe that President Truman, in his message on health, made that statement about five times, I do not know how many times Senator Wagner made the same statement when he was discussing the introduction of his bill to the Senate. "Methinks, the lady doth protest too much," as Shakespeare said. It certainly approaches socialized medicine, it is political medicine, anyway, which is worse. The Government collects the money and pays it out. The Government prescribes the regulations under which physician and patient must act, determines who is a specialist and, in certain instances, even decides who can have a specialist. That part of the bill pertaining to specialists states that the practitioner in charge of the case may summon a specialist, and the patient has no voice in the choice of the specialist. If the patient desires a specialist, he can make application to the nearest governmental agency for the specialist.

Senators Wagner, Murray and Dingell say that there is a free choice of physician. It is a free choice, if the physician agrees to take part in the plan, but not otherwise. Also, a physician can be chosen provided that his panel is not already filled, for the Bill limits the number of patients that a doctor may have. It is free choice, provided that the majority of physicians do not elect to be paid on a capitation basis. I see no possible way of having that without allotting people in a certain area to a certain doctor, which would not be free choice.

RECENT ADVANCES IN THE CARE OF THE SURGICAL COMPLICATIONS OF DIABETES MELLITUS*

LELAND S. MCKITTRICK, M.D.†

BOSTON

MUCH has already been written on the factors involved in the care of the surgical complications of patients with diabetes mellitus. The purpose of this paper is not to review the entire problem but rather to consider the effects of many recent advances in medical science on the care of these patients. I shall confine my remarks to the consideration of the surgical problems.

It is difficult to evaluate the factors that have improved the care of poor-risk and elderly patients in recent years. The security of all patients undergoing surgical procedures has been aided immeasurably by more careful and deliberate preparation for operation, an increasing understanding of fluid balance, parenteral feeding, including the vitamins, whole blood and plasma transfusions, the use of intestinal antiseptics in preparation for resection of the large bowel, and early mobilization. These benefits are shared alike by patients with and without diabetes. It should never be forgotten, however, that the diabetic patient must be evaluated in terms not only of his general and local surgical condition but also of the diabetic state and the facilities at hand to control it before and especially after operation. Increasing experience has convinced me that diabetes mellitus is no contraindication to any surgical procedure whose indications are clear, provided always that the medical, surgical and hospital teamwork is such as to ensure efficient, co-operative care of the patient's metabolic disturbance.

If possible, surgical emergencies are to be avoided. In a patient whose general condition permits the procedure, an operation for gallstones, interval appendicitis, hernia and the like is advised as soon as it can be done under conditions likeliest to assure a safe convalescence.

This discussion chiefly concerns two conditions that are not limited to patients with diabetes but that present particular problems to such patients — operations for which account for over two thirds of the surgical procedures carried out on the diabetic patients at the New England Deaconess Hospital. These conditions comprise infections of the skin and subcutaneous tissue, especially carbuncles, and gangrene and infections of the lower extremities. It is gratifying that the medical advances of the past five years have proved particularly helpful to patients with these complications.

Carbuncles

The 7 deaths among the 95 patients with carbuncles operated on between 1928 and 1941 give no concept of the seriousness of this problem in terms of loss of time and suffering of the patient. It is too early to evaluate the full benefits that penicillin in adequate dosage offers to the patient with a carbuncle. Experience to date at the New England Deaconess Hospital, however, has been most gratifying. We have seen the large, brawny, indurated, painful lesion characteristic of the earlier stages of a large carbuncle completely disappear after control of the diabetes and the daily injection of 100,000 to 300,000 units of penicillin for seven to ten days. Similar lesions in a more advanced stage have resolved into small local painless fluctuant areas 2 or 3 cm. in diameter and have healed promptly after local incision; these lesions, at the worst, would have resulted fatally in 5 to 10 per cent of cases prior to the use of penicillin and, at best, would have cost the patient weeks of hospital care, as well as a wound requiring months for final healing.

To date the cases have been too few and the experience too limited to warrant any definite conclusions. It is adequate, however, to establish a working basis for the management of this type of lesion.

On the basis of this experience any diabetic patient with an early carbuncle is regarded as an emergency and is immediately admitted to the hospital. The diabetes is carefully treated, and daily injections of 300,000 units of penicillin are given in eight equally divided doses until the lesion is operated on or has resolved.

It is to be expected that the greater part of the cellulitis will either disappear completely or leave a broken-down central area that is probably best treated by a small incision, release of the fluid, packing with gauze for twenty-four to forty-eight hours and allowing the skin edges to fall together. This method of handling the small residual cavity has in this limited experience been more satisfactory than attempts to control it by aspiration.

It is quite possible that the small carbuncles that fail to resolve completely and in which necrosis of skin occurs are best treated by excision and early skin graft. If the experience of the past two years is any guide for the future, the extensive operations for large carbuncles previously seen will seldom, if ever, be necessary, except in the badly neglected case.

*From the New England Deaconess Hospital. Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 22, 1946.

†Associate in surgery, Harvard Medical School; surgeon-in-chief, Palmer Memorial Hospital; surgeon, New England Deaconess Hospital; visiting surgeon, Massachusetts General Hospital.

a doctor who could not have afforded it previously, and that the costs would be increased for a while. Then the rate was expected to come down, because the patients would go to a doctor earlier, would not be sick so long and many conditions that they might otherwise have had would be prevented. The rate never did come down, however—in fact, it is still going up. Why? Because it encourages malingering. The number of man-days lost in the United States is 9 per man. In England, before the compulsory sickness insurance went into effect, it was approximately 11, it is now between 14 and 15. In Germany, before compulsory sickness insurance was adopted, it was around 14, and it went up to 28. Consequently, the problem of man-hours lost will not be solved by compulsory sickness insurance, it will be increased rather than decreased.

We all want more medical care, but we want it to be of a high quality. We believe that the program of the American Medical Association, which was released in February, is going to solve that.

The economic aspect of medical care was discussed above, as were preventive medicine and public-health service. Increased aid to the prospective mother is also a necessity. Adequate care in childbirth and proper nutrition to prevent disease in the child should be available on an individual basis, and if the patient is unable to pay for it, help should be given on a community basis, with Federal aid, if necessary, the doctor-patient relation being preserved.

Another point is a proper program for the veteran. I am glad to say that the present officials of the Veterans Administration are anxious to see the veteran taken care of in his own community by his own doctor, and that so far as possible, they are endeavoring to complete this program. They have already worked it out in several states, and they are now in the throes of making arrangements with New York, I hope that you will do the same here—that is, that you will make arrangements with the Veterans Administration on a reasonable basis to both sides, so that the veteran can be taken care of by you in his own community and not be sent to a public institution, unless he has some chronic disease.

Another point is that of research, which, it is generally agreed, should be extended. We are perfectly willing to have Government aid in the matter of research. We want it controlled by a scientific board, and not by a politically appointed director. One should not forget the aid given by the various philanthropic associations, such as the National Tuberculosis Association and the National Foundation for Infantile Paralysis, all of which are per-

forming an excellent service and whose work would be cut off by any national program, making it that much more expensive, because those agencies did it purely on a voluntary contribution basis. One improvement could be made: the organizations should not have a dozen drives each year but one drive for all of them, the money being divided in the proportion actually needed.

Another important factor is education. By education, I mean that not only of the public, but also of the doctor, who is often not informed in these matters. If the average physician is asked whether he is against the Wagner-Murray-Dingell Bill, he will say "Yes." But, if he is asked why, he cannot explain. But physicians must know why they are against it, because the patients are interested. After all, the patient is the one who will decide whether or not the United States is to have socialized medicine, the medical profession will not decide the question. And, the public will get what it wants in the long run. But I cannot believe that the public knows what costs are entailed and what poor medical service will be provided under the proposed national health legislation. And you, gentlemen, must be the ones to tell them about it. Often, the public is not even aware of the facilities that are available.

During the hue and cry when the first Wagner-Murray Bill was introduced, the Medical Society of the State of New Jersey, asked, by way of radio, public speakers and the press, that any person in New Jersey who could not obtain medical care communicate with the Society or one of its county societies, the care being guaranteed. There were only 127 people who said that they could not obtain adequate care, and every one of these could have obtained medical care but did not know how. It is therefore a matter of educating the public of the ways available.

A fact that I have stressed many times and shall continue to stress is that there should be more interest in the county societies. I do not know the situation in New Hampshire, but if it is like that in the rest of the country, the county society is not active and the meetings are poorly attended. It is highly essential that the county society be the activating force in all these matters, otherwise, we are defeated before we start. The physician must be the engine in this whole matter, and he needs the backing of his county society. We must stimulate interest among the members of the medical societies to come out and take an active part and study these questions and know what they are all about, so that when they are called on to discuss them publicly or with the patient individually there need be no fear of what the result will be.

patients (Fig 1) The importance of penicillin in the control of infection in this group is suggested when one realizes that, in routine cultures taken from 75 patients in this group, *Staphylococcus aureus* was present in pure culture in 11 cases or in com-

There was no dorsalis pedis pulsation, but an excellent anatomical and functional result was obtained. Note the long plantar and short dorsal flaps.

bination with other organisms (usually one of the streptococci) in 41 cases

The first transmetatarsal amputation was done in March, 1944. Between then and May 1, 1946, such operations have been performed in 75 cases. Eleven of these were failures, and 1 patient died of coronary heart disease following a higher amputation. The indications for this procedure are not yet completely clear, and in certain cases a small area of necrosis on the dorsal flap (Figs 2 and 3), which has greatly prolonged the healing time, has been disturbing. The indications for the operation will continue to be extended until a careful follow-up study of all patients satisfactorily demonstrates a clear-cut conception regarding when it should or should not be undertaken. The factors involved in the area of necrosis mentioned above are also being studied, in an attempt to eliminate this if possible. A thorough and complete follow-up examination of the late functional results in a large series of patients is also essential before the final evaluation of this procedure can be made.

This experience, however, has been sufficient to cause the conviction that amputation at this level is practical, that with the use of penicillin it is safe that the functional result is good and that it has been and will continue to be a method that—if carefully carried out following proper preparation and under the protection of penicillin in adequate dosage—will obviate amputation at a higher level in many cases. Just how many of this group of 75 patients would have had amputation either through or above the mid-lower leg in previous years is impossible to say, but a review of the records of these patients seems to show quite clearly that at least

FIGURE 2 Areas of Necrosis on the Dorsal Flap of a Transmetatarsal Amputation for Gangrene of the Tops of the First and Second Toes of a Pulseless Foot

This necrosis does not involve the skin of the plantar flap and usually occurs at the site of the more lateral area.

10 to 15 per cent, probably more, of this particular group would have had a major amputation prior to the use of this procedure.

One further improvement in technic should be mentioned. Formerly, when amputation of a digit with the head of its metatarsal was carried out for an infected joint, it was the custom to leave such a wound widely open. This large open wound required weeks, sometimes months, to heal, and in many cases the resulting scar was not good. This was especially true when the foot had been split for removal of the second, third or fourth toe with its

At present the hospitalization of every patient with a carbuncle is strongly favored, with the parenteral use of penicillin rather than local injection or oral administration

Leg Lesions Requiring Major Amputations

In 1934 McKittrick and Pratt¹ carefully analyzed the 57 deaths that had occurred at the New England Deaconess Hospital following operations for lesions in the lower extremities in 622 patients with diabetes mellitus. At that time it was suggested that if some means could be found to control the ever-dangerous infection, the mortality following amputation for gangrene should approximate 5.3 per cent. In the series of operations done between 1923 and 1942 the mortality after amputations through or above the mid-lower leg in 609 cases was 14.1 per cent, whereas that following major and minor amputations in 1036 cases was 9.7 per cent (Table 1). It is interest-

TABLE 1 *Amputations of Lower Extremity in Diabetic Patients (1923-1941)**

OPERATION	NO OF CASES	NO OF DEATHS	MORTALITY %
Amputation of one or more toes	356	8	2.2
Amputation of one or more toes, followed by major amputation	71	7	9.9
Amputation through or above mid lower leg	609	86	14.1
Totals	1036	101	
Average			9.7

ing to compare this with the results during the past five years when these patients had the benefit of the sulfonamides and of penicillin (Table 2).

It is gratifying to note the drop in the mortality after all amputations, from 9.7 per cent to 2.6 per cent, and to observe how closely the mortality of 4.7 per cent for major amputations approximates that of 5.3 per cent suggested ten years

TABLE 2 *Amputations through or above Mid-Lower Leg (1941-1945)*

YEAR	NO OF CASES	NO OF DEATHS
1941	42	1
1942	46	4
1943	44	0
1944	37	2
1945	43	3
Totals	212	10 (4.7 per cent)

previously. This remarkable improvement is considered to be of particular significance, since during this period there have been no important changes in the surgical management of these cases, except those made possible by an increasing ability to eliminate infection as a deciding factor in the type of operation to be carried out. The surgical technic, the

principles of amputation, the anesthesia and to a large degree the personnel* have remained unchanged.

We continue to favor the supracondylar amputation, which is regarded as the easiest, safest operation and the one likeliest to heal promptly without complications. Amputation through the lower leg and the Gritti-Stokes operation are reserved for selected cases. Guillotine amputation through the lower leg for patients in poor condition and with extensive spreading infection is now rarely required because of the effectiveness of penicillin.

Lesions of the Feet Requiring Minor Amputations

The improvement in mortality is not the only benefit that these patients have derived from penicillin. In previous years, experience had repeatedly shown the dangers of carrying out local operation through or near an area of infection in a pulseless foot with poor collateral circulation. It was also apparent that a closed amputation carried out above the infected area usually resulted in satisfactory healing, even though there was little apparent arterial supply at the level of the incision. It therefore seemed only reasonable that if invasive local infection could be eliminated, many more conservative operations could be carried out with safety and with a reasonable chance of success.

The sulfonamides gave protection against certain streptococci but seemed of little help in eliminating the hazards of the more frequent staphylococci. It was therefore not until early 1944, when penicillin

TABLE 3 *All Amputations (1944 and 1945)*

OPERATION	NO OF CASES		NO OF DEATHS	
	1944	1945	1944	1945
Amputation of one or more toes	64	36	1	0
Transmetatarsal amputation	13	36	0	0
Amputation through or above mid lower leg	37	43	2	3
Totals	114	115	3	3
Grand totals	229		6 (2.6 per cent)	

began to be available, that it seemed quite possible that operations could be carried out on certain of these patients with reasonable assurance that the site of amputation could be chosen on the basis of arterial supply alone.

In the group of patients operated on in 1944 and 1945 it will be noted that an operation not mentioned in the previous tables is now frequently carried out (Table 3). This amputation, just proximal to the heads of the metatarsals, is made safe and practical only because virulent invasive local infection and septicemia can now be eliminated from the complications previously so serious for these

MEDICAL EXPERIENCES WITH AMERICAN TROOPS IN THE PACIFIC*

With Remarks on the Diagnostic Value of Sternal Puncture in Malaria and on the Innocuousness of Hookworm Infection

HAROLD D. LEVINE, M.D.†

BOSTON

THIS report is based on patients seen during two years at a large United States Army general hospital in the rich Lockyer River Valley of southern Queensland, seventy miles west of Brisbane, Australia, and during a year and a half of service with another general hospital located first at Lae, on the Huon Gulf in northeastern New Guinea, and later at San Fernando, at the upper extremity of the Lingayen Gulf, Province of La Union, on the Island of Luzon, in the Philippines. Many of the observations made were new to us as individuals, others, to the best of my knowledge, are new to medicine. Alert medical officers, depending on their special interests or training, were able to make crucial observations of certain phenomena of disease, proving some ideas and disproving others. For example, one of my colleagues — a researcher on cancer in peacetime — was able to disprove the idea long held, that betelnut chewing is carcinogenic.¹ A host of other critical observations, by-products of war experiences, will almost certainly come to light in the medical as well as in the ethnologic, anthropologic, geographic and other literature of the next few years. I am sure that many of those who have also served in the tropics could add much of interest to what I have to say about a few of the many fascinating problems met — malaria, hookworm disease, filariasis, diphtheria and scrub typhus fever.

MALARIA

When the Japanese took the East Indies they also took 90 to 95 per cent of the world's quinine. In the face of this fact and with the prospect of much tropical campaigning, the situation in the early days of the war might be described as bleak indeed. True, in the decade before the war some work had been done on the newer synthetic antimalarial drug quinacrine (Atabrine),² but that work had been carried out with native populations that had already developed, naturally, a partial immunity to malaria.

In the early days of the war in the Southwest Pacific the American forces followed a therapeutic antimalarial regimen that the Australians had found quite effective in the Middle East. Quinine was

given for three days in doses of 0.6 gm three times daily, followed by 0.1 gm of quinacrine three times daily for five days and then, because of an alleged incompatibility between quinacrine and plasmochin (pamaquine), by no therapy for two days, finally, 0.01 gm of plasmochin was given three times daily for three days. Although this schedule was modified in many ways, — for example, quinine was given in doses of 0.3 gm three times daily during the two "free" days and concurrently with plasmochin, or this course of active therapy was followed by so-called "suppressive" quinacrine consisting of 0.2 gm twice weekly, — the relapse rate was considerable and the number of man-days of disability from the disease was quite high. In the light of investigations begun in this country by Shannon³ and extended in the Pacific by Bang,⁴ however, utilizing the fluorescent properties of quinacrine to determine its concentration in the blood plasma, it soon became clear that the dosage necessary to attain an optimal effective level was much higher in the primary infections of nonimmune troops than that in natives seasoned to the disease. When the much heavier dosage — 0.4 gm three times during the first day, 0.3 gm three times on the next day, 0.1 gm three times a day for the next four days and 0.1 gm daily indefinitely — was used, the same prompt dramatic antipyretic response was observed that had been consistently noted with quinine. Furthermore, the impression was gained that, by and large, as much could be accomplished by the use of quinacrine alone as with added quinine or plasmochin. Finally, it was found that when the drug was continued in a dosage of 0.1 gm daily, so that, on the average, effective suppressive levels were maintained, the relapse rate became negligible. Consequently, within a few months, instead of being a matter of great concern to the line officers and a major cause of hospitalization, cases of malaria were reported infrequently and were regarded merely as a matter of "poor Atabrine discipline" within a particular command. Before the middle of 1943, then, the malaria problem could quite definitely be said to have been whipped.

The following figures afford an idea of the splendid performance of the United States Army so far as malaria is concerned from January, 1942, through the first seven months of 1945, there were only 207 deaths from malaria in the Army throughout the world, and of these, 20 cases were complicated by

*Read before the Belknap County Medical Society at Leconia, New Hampshire, on April 9, 1946, and before the Medical Staff of the Frisbie Memorial Hospital, Rochester, New Hampshire, on June 11, 1946.

metatarsal head Prior to the introduction of the sulfonamides, the practice of closing the distal portion of such wounds was begun, only the proximal third or half being left open for dependent drainage. Much to our surprise, the sutured portion of the wound healed promptly in spite of the presence of active, although well localized, infection. This "re-roofing" resulted in the saving of weeks of hospital time and in marked improvement in the quality of the final scar. With penicillin, the usefulness of this procedure can be extended and the time spent in preoperative preparation can be shortened (Fig 4).

Anesthesia

Spinal anesthesia continues to be used for all operations on the lower extremities. The injection

FIGURE 3 The Same Stump Shown in Figure 2 Three Months after Revision

Note the excellent final result, as well as the use of a long plantar flap

of 75 mg of procaine crystals dissolved in spinal fluid gives excellent anesthesia of sufficient duration for any of the operations done. It is easy to use and has proved uniformly satisfactory—in fact so much so that we have found no justification for changing to the refrigeration anesthesia developed by Crossman et al.³ and adopted by many clinics throughout the country. In this elderly group of poor-risk patients no preoperative sedation is given, since it is considered to be not only unnecessary but at times dangerous.

* * *

The importance of careful preparation of patients about to undergo elective surgery is stressed.

Marked improvement in the results of the treatment of carbuncles with penicillin is discussed.

A mortality of 4.7 per cent following major amputations for gangrene or infection of lower extremities in 212 cases is compared with a theoretical rate.

FIGURE 4 Amputation of First Toe with Its Metatarsal Head for Osteomyelitis of Metatarso-Phalangeal Joint

The photograph was taken three weeks after the operation. There was excellent circulation to the foot. Note the first-intention healing of the distal two thirds of the wound, which was sutured. The proximal third of the wound on the plantar surface of the foot is not well shown. The cavity was packed loosely with dry gauze at the time of operation, which was removed three days later; it was nearly healed at the time this photograph was taken.

of 5.3 per cent suggested in 1934. A mortality of 2.6 per cent following major and minor amputations in 229 cases was made possible by the discovery of penicillin.

Transmetatarsal amputations have been done in 75 cases since penicillin became available for civilian use. 205 Beacon Street.

MEDICAL EXPERIENCES WITH AMERICAN TROOPS IN THE PACIFIC*

With Remarks on the Diagnostic Value of Sternal Puncture in Malaria and on the Innocuousness of Hookworm Infection

HAROLD D. LEVINE, M.D.†

BOSTON

THIS report is based on patients seen during two years at a large United States Army general hospital in the rich Lockyer River Valley of southern Queensland, seventy miles west of Brisbane, Australia, and during a year and a half of service with another general hospital located first at Lae, on the Huon Gulf in northeastern New Guinea, and later at San Fernando, at the upper extremity of the Lingayen Gulf, Province of La Union, on the Island of Luzon, in the Philippines. Many of the observations made were new to us as individuals, others, to the best of my knowledge, are new to medicine. Alert medical officers, depending on their special interests or training, were able to make crucial observations of certain phenomena of disease, proving some ideas and disproving others. For example, one of my colleagues — a researcher on cancer in peacetime — was able to disprove the idea, long held, that betelnut chewing is carcinogenic.¹ A host of other critical observations, by-products of war experiences, will almost certainly come to light in the medical as well as in the ethnologic, anthropologic, geographic and other literature of the next few years. I am sure that many of those who have also served in the tropics could add much of interest to what I have to say about a few of the many fascinating problems met — malaria, hookworm disease, filariasis, diphtheria and scrub typhus fever.

MALARIA

When the Japanese took the East Indies they also took 90 to 95 per cent of the world's quinine. In the face of this fact and with the prospect of much tropical campaigning, the situation in the early days of the war might be described as bleak indeed. True, in the decade before the war some work had been done on the newer synthetic antimalarial drug quinacrine (Atabrine),² but that work had been carried out with native populations that had already developed, naturally, a partial immunity to malaria.

In the early days of the war in the Southwest Pacific the American forces followed a therapeutic antimalarial regimen that the Australians had found quite effective in the Middle East. Quinine was

given for three days in doses of 0.6 gm three times daily, followed by 0.1 gm of quinacrine three times daily for five days and then, because of an alleged incompatibility between quinacrine and plasmochin (pamaquine), by no therapy for two days, finally, 0.01 gm of plasmochin was given three times daily for three days. Although this schedule was modified in many ways, — for example, quinine was given in doses of 0.3 gm three times daily during the two "free" days and concurrently with plasmochin, or this course of active therapy was followed by so-called "suppressive" quinacrine consisting of 0.2 gm twice weekly, — the relapse rate was considerable and the number of man-days of disability from the disease was quite high. In the light of investigations begun in this country by Shannon³ and extended in the Pacific by Bang,⁴ however, utilizing the fluorescent properties of quinacrine to determine its concentration in the blood plasma, it soon became clear that the dosage necessary to attain an optimal effective level was much higher in the primary infections of nonimmune troops than that in natives seasoned to the disease. When the much heavier dosage — 0.4 gm three times during the first day, 0.3 gm three times on the next day, 0.1 gm three times a day for the next four days and 0.1 gm daily indefinitely — was used, the same prompt dramatic antipyretic response was observed that had been consistently noted with quinine. Furthermore, the impression was gained that, by and large, as much could be accomplished by the use of quinacrine alone as with added quinine or plasmochin. Finally, it was found that when the drug was continued in a dosage of 0.1 gm daily, so that, on the average, effective suppressive levels were maintained, the relapse rate became negligible. Consequently, within a few months, instead of being a matter of great concern to the line officers and a major cause of hospitalization, cases of malaria were reported infrequently and were regarded merely as a matter of "poor Atabrine discipline" within a particular command. Before the middle of 1943, then, the malaria problem could quite definitely be said to have been whipped.

The following figures afford an idea of the splendid performance of the United States Army so far as malaria is concerned from January, 1942, through the first seven months of 1945, there were only 207 deaths from malaria in the Army throughout the world, and of these, 20 cases were complicated by

*Read before the Belknap County Medical Society at Laconia, New Hampshire, on April 9, 1946 and before the Medical Staff of the Frisbie Memorial Hospital, Rochester, New Hampshire on June 11, 1946.

†Assistant in medicine, Harvard Medical School; assistant in medicine, Peter Bent Brigham and Beth Israel hospitals; assistant physician, Boston Dispensary.

scrub typhus fever and can therefore be excluded I do not know how many cases of malaria developed altogether, but the figure was probably in the neighborhood of half a million. This total provides a contrast with the situation in India, where there are a million deaths from malaria every year.

The present recommended dose of quinacrine is somewhat less than that described above. In relapsing malaria it is recommended that 1 gm be given in the first twelve hours, followed by 0.1 gm three times daily for six days and subsequently by 0.1 gm daily for two months. The veteran should be reassured that although he may have further relapses, the process will burn itself out in a year or two. The value of plasmodochin in relapsing malaria is still in the experimental stage. There is some danger in its use, but evidence is now available that it terminates relapses from vivax malaria in a considerable proportion of cases.

During the two-year period of its operation in Australia, there were 18,693 admissions to a large general hospital. In this group there were 3358 cases of malaria — about 18 per cent of the total number. This included 2222 cases of vivax, 286 cases of falciparum and 15 cases of quartan malaria, as well as 59 of mixed types and 776 of types undetermined or unclassified.⁴ Analysis of a representative sample of this material revealed many interesting facts about the symptomatology, vagaries, complications and management of malaria.⁵ Among other aspects studied was the problem of so-called "chronic malaria." In contrast to the native with chronic malaria who presents the classic picture of anemia, malnutrition and asthenia, the Army patients had complaints generally falling in four groups: neurocirculatory asthenia, symptoms referable to the musculoskeletal system, vague symptoms, such as headaches, dizziness, nervousness, insomnia and tremor, referable to the central or autonomic nervous systems, and combinations of two or more of these first three groups. Essentially, these symptoms were noted in the absence of structural organic changes. Prolonged study of these men made it clear that their symptomatology rested on a psychosomatic level. When this was recognized and the patients were treated on that basis, the treatment became more effective from the standpoint of both the individual soldier and the Army. In a much more complete study of the same problem, another group of workers⁶ found that maladjustment to the stresses of the illness and the difficulties of life in the combat hospital area played a major role in the incapacitation of the soldiers with malaria.

A standard teaching before the war was that there is no true causal prophylactic against malaria. Some of the work carried out during the war tended to refute this idea. In a group of so-called "provisional engineers," who went to Milne Bay in New Guinea in May and June, 1943, and who were de-

liberately exposed to malarial infection, a subgroup received no medication and developed malaria in 65 per cent of cases.^{7, 8} In the subgroup that received quinacrine 31 per cent developed attacks of vivax malaria when the drug was discontinued. No patients in the latter group developed malaria while taking the drug during the forty-four-day period of exposure or during the voyage back to Australia, but — and this seems particularly significant — no patient, either during the period of exposure or subsequently, developed falciparum malaria. In an Australian experiment two groups of volunteers were deliberately exposed to falciparum malaria.⁹ Twenty-six received suppressive quinacrine, begun twenty-two to forty-six days before exposure and continued for some time afterward. The other half served as a control and received no medication whatever. None of the former developed clinical falciparum malaria, whereas 100 per cent of the latter developed clinical falciparum malaria after the usual incubation and prepatent period. To use the words of these workers, "The absence of demonstrable parasites, the failure of subinoculation to transmit malaria, and the final demonstration of susceptibility and absence of premunity to the falciparum parasites injected into every volunteer, constituted a chain of evidence indicating that malarial infection had either been prevented by these anti-malarial drugs or cure attained."

A fortuitous circumstance led to an interesting side excursion in malarial research. Captain James R. Lyman had occasion to perform a diagnostic sternal puncture for possible kala-azar in an Australian returnee from the Middle East. The pathological report described, instead of the expected Leishman-Donovan bodies, plasmodium falciparum in the preparation. This surprising finding stimulated an investigation of the value of sternal puncture as a diagnostic procedure in cases in which several routine blood smears failed to show the parasites but in which the possibility of malaria was still strongly suspected.¹⁰ This study was carried out during October, November and December, 1942, with Captain Lyman and Lieutenant Harold E. Young, of the Australian Military Forces, at the 112th Australian General Hospital, where large numbers of Australian soldiers, returned from the Middle East, Ceylon, Malaya and the Indonesian Islands, presented the almost routine problem of whether malaria was present, either as a single entity or in association with some other disease.

At the time this study was interrupted by our recall to our own organization, 11 such cases had been investigated. In these cases, in which thick and thin blood smears failed to show the plasmodium, it was possible to make a definite diagnosis from the bone marrow in 7 cases (Table 1). In 3 in which the bone-marrow puncture was negative (Cases 7, 9 and 10), the subsequent course of events proved that a disease other than malaria had

produced the symptoms. Another patient (Case 8) had had malaria two years previously. Twelve thick and thin smears and the examination of sternal marrow were negative, yet quinine produced a prompt and convincing drop in the temperature. It is therefore obvious that although sternal puncture may bring to light some cases of malaria, it is not infallibly positive in the presence of malarial

precordial pain. Dyspeptic symptoms were also noted by 14 patients, but in 2 of these they were specifically related to combat and in 2 others they antedated military service. Of 34 patients treated and followed, 29 were successfully dewormed and 5 were not. Only 2 of those who were successfully dewormed were rendered free of symptoms. All the others, whether dewormed or not, continued to have the same complaints.

TABLE 1 *The Results of Sternal Puncture in the Diagnosis of Malaria*

6	Benign tertian malaria	1	+
7	Septicemia	4	—
8	Chronic malaria	12	—
9	Chronic malaria ?	4	—
10	Amebic dysentery	3	—
11	Benign tertian malaria	3	+

The second group consisted of 19 patients in the active or convalescent stage of a well defined disease with symptoms limited to those characteristic of that condition, the finding of hookworm infection was merely incidental. This group included 3 cases of infectious hepatitis, 2 of scrub typhus (tsutsugamushi) fever in the convalescent stage, 7 of various skin diseases, 2 of bronchial asthma and 1 each of bacillary dysentery, rheumatoid arthritis, urethritis, migraine and malaria. The subsequent course was typical of the particular disease presented.

The third group included 8 patients whose symptomatology was limited to the gastrointestinal tract. The symptoms comprised postprandial epigastric pain or cramping, periumbilical discomfort, a heavy sensation in the abdomen, gaseous distention and burning sensations in the stomach. Three of these patients were dewormed, and 5 were not. Unfortunately, in most cases in this study, worm burden or ova counts were not made, so that the possible effect of treatment in decreasing the worm burden cannot be stated. Nevertheless, in all cases, the symptoms either were greatly alleviated or disappeared entirely. It must be stated, however, that most of the patients were aware of the diagnosis, and it is possible that the psychotherapeutic effect of a definite treatment for a definite disease contributed to the successful outcome.

infection. No attempt was made to compare the value of this method with that of other methods of detecting obscure cases of malaria, such as the complement-fixation test and examination of the blood smear following epinephrine injection. It is fair to state that subsequent improvement in the accuracy of routine laboratory blood examinations for the malarial plasmodia dampened our interest in sternal puncture. Examination of the literature on our return to this country, however, showed a similar enthusiasm for the method before¹¹⁻¹³ and since¹⁴⁻¹⁶ the onset of the war. Sternal puncture may be regarded as an expedient, safe and rapid method of investigating malaria that may be positive when repeated thick and thin blood smears fail to show the parasites. The method seems to deserve more extensive investigation in the future.

HOOKEWORM INFECTION

In the wake of the Papuan campaign there was, for a time, much preoccupation with the symptomless ovum passer and the attempt to render his stools free of hookworm ova. But the distinction between hookworm disease and hookworm infection and the over-all innocuousness of this infection in our troops were soon appreciated, and the condition dealt with more rationally. Some time later I analyzed a limited series of 70 patients at a general hospital in northeastern British New Guinea.

In the entire group the hemoglobin as determined by the Sahli method ranged from 11.8 to 14.8 gm, with a mean of 13.3 gm. In all but 4 cases the determinations exceeded 12.4 gm. The red-cell count ranged from 3,840,000 to 5,400,000, with a mean of 4,540,000. In only 1 case did the determination fall below 4,150,000. In view of the fact that, from a history of exposure, these patients had had the hookworm infection for from three to thirty months, it seems unlikely that, subsisting on the regular army diet, American troops developed any significant anemia from hookworm.

The symptomatology in this series could be divided into three general groups, the first of which comprised 43 patients with a multiplicity of symptoms, such as nervousness, tremor, apprehension, insomnia, nightmares, battle dreams, somnambulism, headache, dizziness, lethargy, depression, anxiety, temper outbursts, emotional instability and

This observation of lack of anemia is in agreement with the observations of Rhoads et al,¹⁷ who found that, in the presence of an adequate iron balance, anemia does not develop in patients with hookworm infection. In the present study, moreover, it appeared that the only soldiers with hookworm infection in whom treatment was helpful were the small group with purely dyspeptic symptoms. Furthermore, it is generally accepted that in the

absence of reinfection the hookworm eventually dies. The period of parasitism has been regarded as from a few months to several years. It is apparent, then, that from the immediate and long-run point of view, hookworm infection was largely innocuous in American soldiers. Hence the wise and expedient policy eventually formulated of treating ovum passers arbitrarily, of not following the effects of treatment unless the patient was to remain in the hospital for other reasons and of discharging him to duty possibly to have further stool examinations and treatment at a regimental dispensary. In the rare patient with a heavy infection, on the other hand, thorough treatment and adequate follow-up study were necessary.

MISCELLANEOUS DISEASES

Filariasis

A large number of soldiers were seen at the hospital in the summer of 1943 because of the probability of early filariasis. This group had been on Tongatabu, an island of the Samoan group, for exactly a year. Their symptoms were lymphadenitis,¹⁸ with fugitive dome-shaped swellings of the arms and legs, retrograde lymphangitis, varicocele, orchitis, epididymitis and recurrent funiculitis, the spermatic cord becoming enlarged, either spontaneously or after a deliberate exercise test,¹⁹ to several times its normal diameter. In all but 1 case in this entire group, repeated day and night smears failed to reveal the presence of microfilaria. Much more helpful diagnostic aids were the clinical course in soldiers who had been in endemic areas, an intelligently interpreted intradermal test and lymph-node biopsy with the finding of adult filarial worms or a characteristic tissue reaction. These men—familiar with the sight of native Tongans with advanced elephantiasis, envisaging a future behind a wheelbarrow full of scrotum and fearful of sterility in later life—were an extremely unhappy and apprehensive lot. Credit is due Major Paul Kunkel for the understanding and sympathetic way in which this group of soldiers was handled. The patients were told that in the absence of reinfection the likelihood of permanent changes was nil, this reassurance was vindicated by the subsequent course of events, as observed at special convalescent hospitals and elsewhere.^{20, 21}

Diphtheria

It was rather a surprise to learn that diphtheria is an important and widely prevalent tropical disease. Many cases of cutaneous and several of pharyngeal and nasal diphtheria were observed, as well as a few with residual peripheral-nerve palsies and one dying with, if not of, myocarditis. In a thoroughgoing investigation of this disease at Lae in British New Guinea, Cutts²² found that it was indeed the dermatologic wards that served as a constant reservoir of this infection. Cultures from the skin

of many patients with a wide variety of skin diseases showed virulent diphtheria bacilli. The lesions of skin diphtheria seen at this hospital were almost uniformly rather sharply defined, blackish to brownish-black, ulcerated areas with indurated bases,²³ yielding virulent diphtheria bacilli on culture, and located in traumatized areas about the heel or between the toes, where they were spindle shaped, and giving a suggestive if not characteristic appearance. Cutaneous diphtheria must constantly be thought of in the tropics or the diagnosis is apt to be missed.

During this overseas experience a large number of patients were seen with peripheral neuritis, some isolated, some multiple, some involving the scapulo-humeral group and producing the so-called "winged scapula" or involving the peroneal or other groups and some without and some with an elevation of the spinal-fluid protein in association with a normal or only slightly elevated cell count, producing the Guillain-Barré syndrome. In many of these cases early failure of the muscles of accommodation of the eye was suggested by the history or demonstrated by examination. Evidence accumulated during the course of the war became more and more conclusive that these neuritis were the residua of previous diphtheria, usually unrecognized.²⁴ If one is consulted by a veteran complaining of having developed "infantile paralysis" or some obscure neuritis during his tropical experience, it may be helpful to bear this point in mind.

Scrub Typhus Fever

This disease, with a mortality of from 2 to 30 per cent (average, 5 per cent), was far more serious than any other mentioned so far. It is caused by a rickettsia similar to those of epidemic and endemic typhus fever and of Rocky Mountain spotted fever. Its reservoir in New Guinea consists of certain field rats or voles or bandicoots, and its vector is a larval mite that clings, among other sites, to the lower portion of the stalk of the kunai grass, which is abundant on this island. The disease principally affected troops campaigning in uncleared areas. The acute illness is characterized by an eschar developing in a few days after the bite,¹ with marked regional and less marked generalized lymphadenopathy, chills, a high fever, a rash, the development of agglutinins against the Kingsbury strain of *Proteus bacillus*, cough, prostration, deafness, palsies and certain mental symptoms, such as headache, lethargy, delirium and coma. The disease generally runs a remittent course for two weeks, with evidence of pneumonitis and involvement of the cardiovascular system (tachycardia, hypotension, cardiac irregularities and gallop rhythm) supervening during the second week. All grades of severity were encountered, death generally occurring late in the second week. The most prominent post-mortem changes were a generalized

vasculitis and perivasculitis, with lymphocytic and plasma-cell exudation and with a predilection for the lungs, where an interstitial pneumonitis and hemorrhagic edema was produced, for the brain, where focal parenchymatous lesions referred to as "typhus nodules" eventually appeared, and for the heart, where the disease resulted in varying grades of diffuse interstitial or focal perivascular infiltrations of the same cellular types, as well as varying degrees of heart-muscle necrosis. Although there is no question that myocardial damage is present in the acute phase of the disease, the question whether these patients die in acute congestive heart failure is still debated.²⁵ Many of the survivors of this disease were debilitated for months and required prolonged periods of reconditioning before they could return to duty. Clinical²⁶ and pathological²⁵ studies following recovery showed no evidence of persistent myocardial damage and seem to indicate that much of the disability resides in the peripheral vascular system rather than in the heart.

Amebiasis

It should not be forgotten that many patients who have had amebic dysentery will continue to have diarrhea, presumably as a result of residual scarring of the bowel, even after the organism has been eliminated. In any patient with a history of amebic dysentery while in the service it is therefore essential to carry out a sigmoidoscopic examination and, if ulcers are present, to obtain swabbings or washings from the ulcers and to search for the organism. This may prevent the physician from initiating futile treatment. It is also well to remember that some of the drugs used in the treatment of amebiasis, such as chiniofon, are in themselves capable of inducing diarrhea.

* * *

To a civilian, the yellowed, underweight soldier returning from the tropics with a story of rigorous privation, starvation, extreme intolerable heat and disease conjures up an appalling picture of the "dank, steaming" malaria-ridden tropics. And yet the same civilian is amazed at the improvement in this soldier a month or two later, when he has excreted the quinacrine that was merely staining his tissues and when he has regained the weight lost as a normal physiologic reaction to the tropics. Is it possible, one might ask, that the soldier has failed to differentiate the unpleasant effects of field, combat or garrison conditions, with their attendant fatigue and boredom, from those due to the tropics per se? Many of the officers and enlisted men I questioned on this point admitted that life there in peacetime, with their families and with the conveniences and recreations and diet of the civilian, would not be unpleasant.

Interestingly enough, in spite of the high temperatures and humidities, no genuine cases of heat

stroke or heat exhaustion were observed during this service in New Guinea, Luzon and in semitropical Australia, presumably owing to an adequate process of acclimatization in the troops. Nor did the occasional elevations of temperature that had been expected on extremely hot days occur. In fact, many of my associates agreed that the days were much more comfortable than the so-called "dog days" of July or August in Washington or even in Boston.

SUMMARY

Medical experience in the Pacific in World War II has extended the knowledge of certain tropical diseases. Among other observations the following are noteworthy.

Quinacrine (Atabrine), at first regarded as a makeshift substitute for quinine, was found to be a more effective therapeutic and suppressive agent than the latter against malaria and eventually made that disease a relatively unimportant military problem.

So-called "chronic malaria" as it existed in American troops differed from the classic picture instead of anemia, malnutrition and asthenia, the troops presented various psychosomatic patterns largely without demonstrable organic disease.

Sternal puncture may reveal malarial plasmodia when repeated thick and thin blood smears fail to show the organism. In experienced hands, however, repeated thick and thin smears are satisfactory in the vast majority of cases.

Hookworm infection is to be distinguished from the hookworm disease. Parasitism is largely innocuous in American troops. Only parasitized troops with purely dyspeptic symptoms may expect relief from their symptoms after treatment.

Day and night blood smears are almost invariably negative in early filariasis. Lymph-node biopsy, the typical clinical course and skin tests, intelligently interpreted, are much more helpful in arriving at the diagnosis. Although fear of chronic invalidism was prominent in the minds of infected soldiers, evidence at hand indicates that permanent residua are unlikely.

Cutaneous diphtheria and, to a lesser extent, nasal and pharyngeal diphtheria are important tropical diseases. The dermatologic wards form a constant reservoir for the organism. Many cases of unrecognized diphtheria are followed by obscure neuritides, some with a Guillain-Barré type of spinal-fluid pattern.

Scrub typhus (tsutsugamushi) fever may produce severe fatal lesions of the heart, lungs or brain. There is neither clinical nor pathologic evidence of persistent heart disease following the infection.

MEDICAL PROGRESS

DIGITALIS*

A. S. FREEDBERG, M.D.,† AND PAUL M. ZOLL, M.D.‡

BOSTON

IN RECENT years many reports have appeared on new purified digitalis preparations. Revisions have also been made in the *USP* unit of potency of digitalis, with changes in the method of assay as well as in the strength of the official preparation. Many cases of severe toxicity from digitalis have recently been reported¹⁻⁵ that indicate considerable confusion regarding the choice and dose of digitalis substances. It is the purpose of this paper to discuss the present status of whole-leaf digitalis and several purified digitalis bodies.

ASSAY

In the twelfth revision (1942) of the *United States Pharmacopoeia* the cat method of assay was employed for the first time. One cat unit is defined as the amount of digitalis per kilogram of cat weight that produces a lethal effect under certain defined conditions. One *USP XII* unit of digitalis represents the same potency as 0.1 gm of the *USP* digitalis reference standard powder, when assayed as directed. The digitalis leaves from which the reference powder was made, however, were of high potency, so that 1 *USP XII* unit is equivalent to 20 per cent more than 1 cat unit. It is particularly important for the physician to know the digitalis preparation he is using, since the clinical effect of

digitalis, standardized according to *USP XII*, is approximately 25 per cent weaker than *USP XI*, which in turn is approximately 50 per cent stronger than *USP X*.

The latest revision has led to more uniform preparations but has not solved the difficulties of assay. There are many variables inherent in the technic of assay by the cat method, such as the rate of injection,^{6,7} body temperature of the animal⁸ and depth and type of anesthesia. The increased toxicity of digitalis observed in cats with elevated body temperatures may be of clinical significance in explaining the deleterious effect of digitalis in patients with febrile illnesses. Further objections may be raised that the cat method of assay measures the lethal potency of digitalis and not specific therapeutic action.⁹⁻¹⁵ Bio-assays by other methods¹⁵⁻¹⁷ offer no advantages over the standardized cat procedure.

A chemical assay based on the presence of an active hydrogen atom in the unsaturated lactone group in digitalis has been developed.¹⁸ Further studies have shown, however, that the proposed chemical method does not measure total biologic activity¹⁹ and does not yield consistent results.²⁰

Human Method

Since the cat method of assay involves intravenous injection of digitalis substances, differences in absorption of the drugs from the gastrointestinal tract are not taken into account. Completely non-absorbable fractions may have significant potency according to the cat method of assay.²¹ Gold²²

showed the error in translating potency of digitalis from cat units to clinical potency in man, by comparative assays in cats and human beings, a group of digitalis preparations with the same strength in cat units showed a tenfold range in potency in human subjects

The assay of digitalis preparations in human subjects has been developed by measuring the effect on the electrocardiogram. Bromer and Blumgart,²³ using the three standard leads, found that changes in the T wave of the electrocardiogram could be used as a quantitative index of the amount of digitalis effective within the body. In other studies,^{24, 25} which failed to demonstrate a quantitative correlation between the amount of the drug and the resultant electrocardiographic effects, only Lead 2 was recorded.^{24, 25} Although effects with digitalis were inconstant in the standard leads, Goldberger²⁶ noted the constant production of changes in the T waves and the ST segments in unipolar limb leads. More recently the quantitative effects of a digitalis substance on the electrocardiogram were measured by the analysis of the ventricular gradient.²⁷ This method is not yet suitable for human assay of digitalis.

Satisfactory assays in normal human subjects have been accomplished by Gold,^{28, 29} who produced qualitatively similar effects on the T wave and the ST segment with known and unknown preparations of digitalis. After control tracings (Leads 1 and 2) a dose of digitalis was given and the electrocardiogram repeated in twenty-four hours. In four experiments on the same subject, the electrocardiographic changes induced by doses of 100 per cent, 122 per cent and 149 per cent of a standard preparation of digitalis were compared with those following the digitalis substances to be assayed. The unknown preparations of digitalis were thereby assayed in human beings with an error of 25 per cent. Geiger et al.,³⁰ on the other hand, concluded that progressive digitalization produced electrocardiographic changes that were too small and inconstant to yield any quantitative correlation. A review of their actual data reveals, however, that in 3 of 10 normal subjects progressive digitalization caused increasing changes in the T waves. It was through the use of a few selected subjects like these that Gold was able to assay digitalis in human beings.

It is clear that such an assay is desirable because of the closer parallelism with clinical experience. Although the method proposed by Gold is the best available at present, its results have not yet been confirmed, it requires time, and relatively few subjects are suitable for assay. Furthermore, since the estimation of the electrocardiographic effect of digitalis depends on the judgment of the electrocardiographer regarding when equivalent changes in the T wave are produced, other causes of T-wave changes must be excluded. These include spontaneous variations and those induced by changes

in heart rate, as well as by food, drink, exercise, excitement, infections and fever, position and hyperventilation.³¹⁻³⁶

CARDIODYNAMIC EFFECTS

Since the assay of digitalis by the cat method is still imperfect and does not exactly reflect the clinical potency of the drug, the physician's skill is of paramount importance in the therapeutic use of digitalis. The rational use of digitalis demands understanding of its effects on the cardiovascular dynamics in congestive heart failure in human subjects.

It is almost universally agreed that administration of whole-leaf digitalis and purified glycosides in patients with congestive heart failure results in an increased cardiac output or a decrease in arteriovenous oxygen difference,³⁷⁻⁴⁹ lowered venous pressure^{41, 40, 43, 46, 47, 50-54} a faster circulation time^{41, 40, 47, 53, 54} and a diminished blood volume.^{55, 56} The fall in venous pressure may precede diuresis and slowing of the pulse rate.^{43, 51, 52, 54} Recently, Stewart et al.¹⁴ reported an increase in peripheral circulation as a whole after digitalization. The increase in cardiac output is obtained without a proportionate increase in cardiac work or oxygen consumption. The failure of cardiac output to return completely to normal after digitalis⁵¹ confirms the clinical evidence that most patients with congestive failure require additional therapy, such as limitation of activity, salt restriction and diuretics.

After digitalization the vital capacity is increased,^{45, 47} the respiratory minute volume is reduced^{38, 47, 57} and the alveolar carbon dioxide content is increased.⁴⁴ The basal metabolic rate falls.^{44, 44} Digitalization results in a decreased oxygen debt after exercise.⁵⁸

In patients with auricular fibrillation and a rapid ventricular rate digitalis induces significant slowing of the pulse rate. This effect has a twofold origin: vagal stimulation by therapeutic^{59, 60} or subtherapeutic^{61, 62} doses, which may be obliterated by atropine or exercise, and a direct action on the nodal tissues and myocardium, which cannot be obliterated thereby.

Considerable controversy exists concerning the exact mechanisms of the action of digitalis. According to some observers the therapeutic effect of digitalis is extracardiac in origin. Dock and Tainter^{63, 64} proposed another mechanism of action of digitalis — hepatic-vein constriction, with consequent reduction in venous return and in right auricular venous pressure, an effect comparable to venesection. Among other objections to this hypothesis is evidence that this mechanism does not obtain in human subjects.^{65, 66} The effects on vagal activity and the conducting tissues of the heart mentioned above do not account entirely for the beneficial response, which may occur without or before a change in rate. A large body of physiologic⁶⁷⁻⁶⁹ and electrocardiographic^{27, 70} data indicates a direct action of digi-

MEDICAL PROGRESS

DIGITALIS*

A S FREEDBERG, M D,† AND PAUL M ZOLL, M D ‡

BOSTON

IN RECENT years many reports have appeared on new purified digitalis preparations. Revisions have also been made in the *USP* unit of potency of digitalis, with changes in the method of assay as well as in the strength of the official preparation. Many cases of severe toxicity from digitalis have recently been reported¹⁻⁵ that indicate considerable confusion regarding the choice and dose of digitalis substances. It is the purpose of this paper to discuss the present status of whole-leaf digitalis and several purified digitalis bodies.

ASSAY

In the twelfth revision (1942) of the *United States Pharmacopoeia* the cat method of assay was employed for the first time. One cat unit is defined as the amount of digitalis per kilogram of cat weight that produces a lethal effect under certain defined conditions. One *USP XII* unit of digitalis represents the same potency as 0.1 gm of the *USP* digitalis reference standard powder, when assayed as directed. The digitalis leaves from which the reference powder was made, however, were of high potency, so that 1 *USP XII* unit is equivalent to 20 per cent more than 1 cat unit. It is particularly important for the physician to know the digitalis preparation he is using, since the clinical effect of

digitalis, standardized according to *USP XII*, is approximately 25 per cent weaker than *USP XI*, which in turn is approximately 50 per cent stronger than *USP X*.

The latest revision has led to more uniform preparations but has not solved the difficulties of assay. There are many variables inherent in the technique of assay by the cat method, such as the rate of injection,^{6,7} body temperature of the animal⁸ and depth and type of anesthesia. The increased toxicity of digitalis observed in cats with elevated body temperatures may be of clinical significance in explaining the deleterious effect of digitalis in patients with febrile illnesses. Further objections may be raised that the cat method of assay measures the lethal potency of digitalis and not specific therapeutic action.⁹⁻¹⁶ Bio-assays by other methods¹⁵⁻¹⁷ offer no advantages over the standardized cat procedure.

A chemical assay based on the presence of an active hydrogen atom in the unsaturated lactone group in digitalis has been developed.¹⁸ Further studies have shown, however, that the proposed chemical method does not measure total biologic activity¹⁹ and does not yield consistent results.²⁰

Human Method

Since the cat method of assay involves intravenous injection of digitalis substances, differences in absorption of the drugs from the gastrointestinal tract are not taken into account. Completely non-absorbable fractions may have significant potency according to the cat method of assay.²¹ Gold²²

0.5 mg for immediate digitalization^{30 51, 101, 109-112}, 0.1 mg may be administered every half hour to hour thereafter until full digitalization is accomplished. The short duration of action raises the problem of subsequent maintenance of digitalization. For this purpose, it has been recommended that, together with 0.5 mg of ouabain intravenously, whole-leaf digitalis be given orally — $\frac{1}{4}$ cat units to patients weighing less than 125 pounds, 6 to patients weighing 125 to 175 pounds, and 8 to patients weighing more than 175 pounds^{53, 109, 110}. At the end of twenty-four hours the patient may be placed on a daily maintenance dose of whole-leaf digitalis.

The only advantage possessed by the strophanthins over other purified glycosides is the rapid onset of action. Many considerations, however, make them unacceptable to the physician. Their stability in solution has been questioned¹⁰³. They are irritating when deposited extravascularly. Finally, maintenance of digitalization is difficult as a result of the short duration of action. Combinations with whole-leaf digitalis or other slowly acting drugs are difficult and unsatisfactory for routine use in that they often lead to toxicity or lack of adequate digitalization. In the relatively few emergencies in the treatment of congestive heart failure or paroxysmal arrhythmias, therefore, the physician uses to better advantage one of the other more stable, less irritating, purified glycosides with rapid and prolonged action.

LANATOSIDE C

Lanatoside C (digilanid C or Cedilanid) is the only one of the three lanatosides occurring in *Digitalis lanata* that is not present in *Dig. purpurea*. Many studies stimulated by the work of Moe and Visscher^{9 10} have been made comparing the potency, absorption from the gastrointestinal tract, speed of action and elimination, type of cardiac effect, therapeutic to toxic ratio, toxic effect and clinical effectiveness of lanatoside C with those of other preparations.

Absorption and Potency

Although the absorption of lanatoside C in animals¹¹³ is much faster and more complete than that of whole-leaf digitalis, studies in human subjects have yielded conflicting results¹¹⁴⁻¹¹⁸. The intravenous digitalizing dose in man of lanatoside C is agreed to be 6 cat units (16 mg), somewhat more than the oral and intravenous digitalizing dose of 3 cat units (12 mg) for digitoxin^{22 55, 116}. The single oral digitalizing dose for lanatoside C varied from 5 to 10 mg^{22 114 117}. The threefold to sixfold increase in oral over intravenous dose is due presumably to poor and variable absorption of the drug. It must be concluded that the absorption of lanatoside C is much less complete and more variable than that of digitoxin.

Time of Action

Accurate information is available regarding the relative speed and duration of action of lanatoside C. Following intravenous injection, the earliest effects were noted in ten to thirty minutes. This onset of action was measured by the fall in venous pressure,^{40 51 52 65, 69} slowing of ventricular rate,^{51 52 70} increased cardiac output,^{40 65, 69} diminution in diastolic heart volume or oxygen consumption,^{40, 65 69 113} and electrocardiographic changes.^{24 70} The effect is maximal in approximately two hours,⁷⁰ persists sixteen²⁴ to thirty-six hours⁷⁰ and disappears in three to six days.⁷⁰ In comparison with that of other glycosides, the onset of action of lanatoside C is slower than that of ouabain, similar to that of digoxin and considerably faster than that of digitoxin, the duration of effect is longer than that of ouabain and digoxin but considerably shorter than that of digitoxin.

Toxicity

No differences were found in the production of myocardial cellular damage¹¹⁹⁻¹²¹ and associated electrocardiographic changes^{122 123} by toxic doses of various glycosides, including lanatoside C. Kyser et al.¹²¹ related the probable mechanism to vagal stimulation and coronary constriction, since the lesions could be prevented by atropine or purines given at the same time as the digitalis drugs.

The prolonged intravenous administration of lanatoside C to dogs in small doses for over a year produced no harmful effect on the myocardium.¹²⁰ As with other glycosides, it does not reduce coronary blood flow at therapeutic or subtoxic levels.^{124 125}

In its ratio of minimal therapeutic to toxic dose, lanatoside C ranked next to ouabain and far above lanatosides A and B.^{9 10} Cattell and Gold,¹⁵ however, were able to demonstrate no difference in the ratio of therapeutic to toxic dose of a large number of cardiac glycosides, including lanatoside C. Nevertheless, many effects that contribute to the total toxic action of digitalis bodies cannot be observed in the experimental method employed.

Clinical Use

For intravenous digitalization 1.2 to 1.6 mg may be followed by subsequent administration of 0.4 mg at intervals of four to eight hours until the full digitalizing effect is noted. In this way, complete digitalization is rapidly reached and danger of toxicity reduced in spite of individual variations in susceptibility to the drug. Although 7.5 to 10.0 mg in two or three days is recommended in most studies for oral digitalization with lanatoside C, it has already been noted that there is a wide range in the required dosage. The broad range in the daily maintenance dose, from 0.5 to 3.0 mg, indicates the difficulty in maintenance of digitalization. This may be due to the rapid elimination and poor absorption of lanatoside C.

talism on heart muscle In this connection, Guttman⁷¹ has demonstrated the chemical union between digitoxin and striated muscle, such a combination with heart muscle has not yet been reported

WHOLE-LEAF DIGITALIS

Indications

In the light of the cardiodynamic effects of digitalis, it may be stated that the primary indication for the clinical use of digitalis is congestive heart failure Sufficient data are available to indicate the beneficial action of digitalis in congestive failure irrespective of the etiology of the disease or the type of cardiac rhythm^{4, 72-80} Additional indications include auricular flutter, persistent auricular fibrillation and heart disease associated with hypertension or valvular disease to prevent cardiac hypertrophy and congestive failure⁸¹⁻⁸³

Digitalis substances have been used successfully in the treatment and prevention of episodes of paroxysmal auricular tachycardia and paroxysmal auricular fibrillation^{80, 84-87} Although it has been assumed that the beneficial action in auricular arrhythmias is related to vagal stimulation, the mechanism of the action has not been established⁸⁸ The changes in cardiovascular dynamics that occur with constrictive pericarditis in the absence of auricular fibrillation, thyrotoxicosis, infection, shock and anemia are not indications for the use of digitalis

Contraindications

It should be stressed that there are no absolute contraindications to the use of digitalis in the presence of congestive heart failure In the absence of congestive failure contraindications include multiple ventricular extrasystoles and ventricular tachycardia, angina pectoris^{89, 90} or myocardial infarction,^{89, 91} recent or old, hypersensitivity of the carotid sinus,⁹² Stokes-Adams syndrome and partial heart block⁹³ Blumgart and Altschule,⁹⁴ however, showed that the administration of therapeutic amounts of whole-leaf digitalis to patients with partial heart block was not followed by an increase in the block

The effect of digitalis on intravascular clotting has recently been the subject of considerable investigation It has not yet been established that digitalis significantly alters the blood coagulation time⁹⁵⁻¹⁰⁰ It has been suggested that digitalis is a factor in the formation of fatal emboli by its thromboplastic effect or by the mobilization of endocardial thrombi^{91, 101, 102} The clinical data presented are not decisive

Clinical Use

Many schedules have been devised for the administration of digitalis^{80, 103-105} It must be remembered that routine administration strictly according to a preconceived plan is not advisable because of

variations in the drug and in the patient In most cases of congestive heart failure in which the drug has not been previously administered, digitalization may be accomplished by giving 0.3 gm of digitalis purpurea (*USP XII*) three times the first day and 0.1 gm three times daily thereafter until the optimal therapeutic effect or symptoms of minor toxicity appear Such a scheme avoids excessive delay in therapeutic result and also minimizes the risk of undesirable toxic manifestations In patients with auricular fibrillation and a rapid ventricular rate, slowing of the ventricular rate approximately to 70 is a satisfactory end point In patients with normal rhythm or with auricular fibrillation and slow ventricular rate, evidence of satisfactory digitalization consists of marked clinical improvement or the appearance of early toxic manifestations, such as anorexia and extrasystoles When a clear end point is reached, the drug may be discontinued for a day, if necessary, and a daily maintenance dose of 0.1 to 0.2 gm administered

A reliable preparation of whole-leaf digitalis should be used with which the physician is familiar, changing from one preparation to another is undesirable In the few cases in which whole-leaf digitalis is not tolerated or more rapid digitalization is needed a purified glycoside is preferable, either in a single oral dose or intravenously Recently, many purified preparations of digitalis bodies have been offered to the physician These are crystalline, do not require biologic assay and can be prescribed in terms of weight of the drug

STROPHANTHINS

Ouabain is obtained in pure crystalline form from *Acocanthera ouabain* and *Strophanthus gratus* From *Strophanthus kombé* is obtained K-strophanthin, an amorphous mixture of glycosides K-strophanthin-alpha (Cymarín), K-strophanthin-beta and K-strophanthoside are pure crystalline glycosides that have been isolated from this mixture The absorption of all these substances from the gastrointestinal tract is so irregular and poor that they are not suitable for oral use^{106, 107} Recently, Gold et al¹⁰⁸ studied a series of synthetic esters of the aglycone strophanthidin, one of which — the benzoate ester — was somewhat effective orally

Although the strophanthins induce the same qualitative physiologic effects after intravenous injection as digitalis, quantitative differences exist They are the most rapidly acting glycosides, inducing a decrease in ventricular rate and venous pressure in the first three or four minutes after administration,⁶¹ with a maximum effect in thirty⁶² to one hundred and twenty minutes⁶³ and a total duration of effect from twenty-four to seventy-two hours^{109, 110}

Clinical Use

It has been recommended that K-strophanthin or ouabain be given intravenously in doses of 0.3 to

The potency of 1 mg of digitoxin is approximately equal to 1000 mg of *USP XIII* digitalis reference powder. Thus, 125 mg of digitoxin induces the same degree of reduction of ventricular rate as 125 gm, or 163 cat units, of whole-leaf digitalis. The cumulative action of digitoxin is similar to that of whole-leaf digitalis, in patients with auricular fibrillation, the administration of small daily doses — 0.2 mg — resulted in a gradual decline of ventricular rate to normal levels in about three weeks.^{124 128} Maintenance of this dosage during a subsequent prolonged period induced no further change of rate. It may therefore be concluded that the excretion of digitoxin, like that of whole-leaf digitalis, is a function of the amount available within the body rather than the amount administered. Gold et al.¹²⁸ found no significant difference in the ratio between the toxic and therapeutic dose for digitoxin as compared to digitalis.

Toxicity

The toxic actions of digitoxin were first observed by Koppe,¹²⁹ who took 3.5 mg in five days, suffering severe toxic symptoms, nausea and vomiting, a slowing of the pulse rate from 80 to 40 and a bigeminal rhythm that became grossly irregular. Gold^{67 127} noted that a single oral digitalizing dose of digitoxin of 1.26 mg, or 3 cat units, induced nausea within two hours in only 2 per cent of a large series of patients. This was presumably due to the local gastric emetic action of digitoxin. An equivalent dose of whole-leaf digitalis produced early nausea in 20 per cent of the same group. With a single dose of 2 mg of digitoxin, 32 per cent of the patients developed minor toxic symptoms, and 20 per cent vomited. There seems to be ample evidence that digitoxin induces the same incidence of late or central toxicity as whole-leaf digitalis.^{140 141} Toxic doses of digitoxin, as with other glycosides, administered to animals are associated with the development of myocardial lesions,^{119 121} changes in the ST and T waves^{122 123} and a reduction in coronary blood flow.¹²⁵

Clinical Use

Stroud and VanderVeer¹²⁰ observed that the digitalizing dose of digitoxin was 1.3 to 2.2 mg when given orally over a period of three to six days. The maintenance dose was 0.1 mg daily. In many hundreds of patients with auricular fibrillation and a rapid ventricular rate Gold et al.^{124 128} found that a single oral or intravenous dose of 1.2 mg carried the process of digitalization fairly far.¹²⁴ They recommended subsequent daily doses of 0.2 mg to complete and maintain full digitalization. It must be remembered that full digitalization cannot be achieved promptly by this routine in all cases.^{59 125 141} In undigitalized patients, a single dose of 1.2 mg may be given by oral or intravenous route. The subsequent administration of digitoxin to

achieve full digitalization depends for its end point on whether the patient has auricular fibrillation with a rapid ventricular rate, auricular fibrillation with a slow ventricular rate or normal rhythm. In the presence of auricular fibrillation with a rapid ventricular rate, 0.2 to 0.4 mg should be administered at intervals of six to eight hours until the ventricular rate reaches approximately 70, it is not necessary to carry such patients to the point of minor toxicity. To complete full digitalization in patients with auricular fibrillation and a slow ventricular rate or with normal rhythm, additional digitoxin, in a dose of 0.2 to 0.4 mg, must be administered at intervals of six to eight hours until the earliest toxic symptoms are produced. It must be kept in mind that the desired clinical response may occur as a result of partial digitalization. In our experience, the subsequent maintenance dose has varied from 0.1 to 0.4 mg daily. In addition, despite the stated cumulative action of digitoxin, it has been necessary to redigitalize some patients with congestive failure at intervals of four to six months, even though they have been on large, apparently adequate, maintenance doses. When patients with auricular fibrillation become ambulatory close observation of the effect of exercise on the ventricular rate is necessary.⁵⁹⁻⁶¹ A sufficiently large maintenance dose should be administered so that exercise does not produce an excessive rise in ventricular rate.

In summary, the advantages of digitoxin are that it is a pure chemical that is stable and does not require bio-assay and that it is completely absorbed from the gastrointestinal tract, so that the oral and intravenous doses are the same and interchangeable. Furthermore, the small amount of digitoxin necessary for digitalization permits administration of a large fraction in a single dose, with only a small incidence of local gastrointestinal irritation. The rapid onset of action makes for quick digitalization by the oral route so that intravenous administration is rarely necessary. The prolonged duration of action, like that of whole-leaf digitalis, makes for easy maintenance. It is thus the drug of choice when a purified preparation is desired. Since there is some evidence that various preparations of digitoxin differ in potency, it is advisable for the physician, as with whole-leaf digitalis, to use a single preparation with whose action and potency he is familiar. The cost of digitoxin is at present considerably more than that of whole-leaf digitalis.

Particular stress has been placed on the value of digitalis, particularly intravenous lanatoside C, for its rapid action in arrhythmias, such as paroxysmal auricular tachycardia, auricular flutter and auricular fibrillation, and even in chronic auricular flutter and fibrillation^{24, 80, 85, 87} Full digitalization was accomplished at the onset of the paroxysm and maintained by the daily use of 0.5 to 1.0 mg. over long periods. Although this schedule reduced the incidence of paroxysms, there is no evidence that lanatoside C accomplishes more than other digitalis preparations in the treatment of auricular disorders.

In summary, lanatoside C is a potent glycoside with all the actions of digitalis preparations. The advantages claimed, such as a greater margin of safety, greater cardiac efficiency and lack of reduction of coronary blood flow, are not yet proved in clinical practice. It is rapidly although poorly absorbed from the gastrointestinal tract. The relatively rapid excretion of lanatoside C, although perhaps a factor of safety in reducing the incidence and duration of toxic manifestations, is also a disadvantage, since maintenance of digitalization is difficult. The rapidity of effect on intravenous administration makes lanatoside C preferable to digitoxin in the relatively few acute emergencies in which the time differential may be important.

DIGOXIN

Digoxin, a purified glycoside isolated from lanatoside C by hydrolysis, is apparently the active cardiac principle in lanatoside C. Its physiologic effects on the heart and its toxic manifestations are similar qualitatively to those of the other digitalis bodies^{25, 43, 51, 52, 70, 126, 127}. Quantitative differences in the rate and extent of absorption from the gastrointestinal tract, as well as in the rate of elimination, differentiate digoxin from the others in clinical application.

Time of Action

Digoxin is similar to lanatoside C in its speed and duration of action, its effects become apparent in three to thirty minutes, are maximal in approximately one and a half to five hours and regress as early as eight to ten hours, being largely gone in twenty-four to thirty-six hours and completely absent in two to six days. These actions are appreciably more rapid than those of digitoxin. Batterman and DeGraff¹²⁸ clearly demonstrated the relatively rapid rate of elimination of digoxin. They digitalized 38 patients to the point of minor toxicity by giving 0.5 to 1.0 mg. of digoxin every six hours. After varying intervals, they repeated the administration with the same schedule to the same level of toxicity. The fraction of the initial dose necessary to reproduce the same level of toxicity after intervals of twenty-four, forty-eight and seventy-two hours was 49, 84 and 87 per cent respectively. These percentages indicate the amounts of the

drug lost in the intervals of time. The rapid elimination of the drug was further demonstrated in that, when an adequate single daily maintenance dose was given in divided portions, it became obviously insufficient, with resultant reappearance of congestive failure. This study is particularly cogent since a clear-cut, readily reproducible end point—namely, minor toxicity—was used, so that the same level of digitalization was clearly obtained even under conditions of clinical study. The usual objections to so many clinical investigations were avoided in that undefined levels of “full digitalization,” “desired cardiac effects” and “improvement in congestive failure” were not used.

Clinical Use

Many studies have clarified the clinical effectiveness of digoxin^{54, 78, 80, 104, 125, 127, 129, 130}. The average therapeutic and toxic doses on rapid oral administration were 3.75 and 6.0 mg. respectively, 1.0 to 2.0 mg. may be given initially, followed by 0.5 mg. every six hours until the desired effects are produced¹⁰⁴. For intravenous digitalization 1.0 mg. may be injected, followed by 0.5 mg. every six hours as necessary. The oral maintenance dose varied from 0.25 to 1.25 mg. daily. In some cases as much as 1.0 mg. three times daily was necessary for maintenance of digitalization¹⁰⁴.

In summary, digoxin is a potent substance that is valuable for rapid digitalization, with no particular advantage over lanatoside C. Its relative insolubility and irritating character make intravenous administration difficult. The difficulty of maintaining full digitalization over the long periods necessary in chronic congestive heart failure is a serious disadvantage.

DIGITOXIN

Digitoxin, or *digitaline crystallisée*, was isolated by Nativelle^{131, 132} in 1866 and was proved to be a potent cardiac drug by Vulpian.¹³¹ In 1875 Schmiedeberg¹³³ isolated a crystalline substance from digitalis leaves, which he named digitoxin, and stated that it formed the bulk of *digitaline crystallisée*. Although some data^{106, 134, 135} indicate that preparations of *digitaline crystallisée* and digitoxin differ in potency, the *United States Pharmacopoeia* treats them as if they were the same.

Pharmacology

Digitoxin is completely absorbed from the gastrointestinal tract in animals and human beings. Thus, the intravenous and oral doses are the same¹³⁵. If the oral absorption of digitoxin is judged by the decline in ventricular rate, it is complete in four to ten hours^{136, 137}. On intravenous injection the initial effects were noted in twenty-five minutes to two hours, with maximal effects in two to nine hours. Regression of effect began in two or three days, the total duration of action lasting approximately two weeks^{51, 67, 70, 134}.

dilated, is displaced anteriorly, suggesting a retroperitoneal origin for the mass. The barium-enema study is rather unsatisfactory, probably because the patient was unable to hold the barium. The column ends in the descending colon, and so far as I can make out, there is no evidence of intrinsic disease, although there is marked displacement, as described in the record.

DR TAYLOR: This is a long history, and yet it includes few positive findings. The background of India is canceled out by the facts that no tropical

nauseated and vomited. Otherwise, the only findings were the large hard, partly fixed mass in the pelvis and the elevation of the white-cell count to 18,300.

What caused the pelvic mass? The elevated white-cell count at once makes us wonder whether an inflammatory mass was involved. If this patient had been older and had presented x-ray evidence of a diverticulum, one would wonder if the mass had arisen from diverticulitis of the colon, which sometimes causes large masses. The surprisingly

FIGURE 1

diseases are mentioned and that the patient had always been well while there. The examination by the flight surgeon before departure from India, with the finding of no abnormalities, should probably not be seriously considered. I believe that the flight surgeons may have overlooked masses the size of a grapefruit or watermelon. The patient did have a mass when he arrived in this country, however, and was astute enough to recognize it himself. The only preceding episode was the brief attack of knife-like pain followed by the passage of flatus on the trip home. In the hospital, the patient felt

negative history of any relation to episodes of inflammation in the past, however, makes one doubt that. Similarly, an appendiceal abscess frequently gives rise to a large mass, but again there is nothing in the background except for one brief episode of pain. If we had to go seriously into the background of tropical diseases I should not know what to call a mass originating in a patient who had been in India. If he had been in South America, one would wonder about echinococcal disease in some form. Certainly against inflammatory disease is the absence of anything suggesting an inflammatory

CASE 32521

PRESENTATION OF CASE

A forty-five-year-old schoolmaster entered the hospital because of an abdominal mass associated with crampy abdominal pain.

Thirty days before admission the patient had had a short attack of knifelike suprapubic pain that was accompanied by the passage of considerable gas by rectum. At that time he was en route from India to the United States. He had served in India for three years with the United States Army Air Force during which time he had felt entirely well and had had no tropical diseases. Examination had been carried out by a flight surgeon shortly before departure, and no abnormalities had been noted. On arrival in the United States the patient noticed the appearance of a lower abdominal mass. This was called to the attention of a physician, who found a nontender symmetrical mass in the suprapubic area about the size of a large grapefruit, this extended to the umbilicus. The patient was referred to a genitourinary consultant, who catheterized the bladder and found no residual urine. The mass did not change on catheterization. The patient was then referred to the hospital. On entry he stated that the day before admission he had felt nauseated and had vomited twice, this was the only episode of nausea and vomiting that had occurred. The bowel movements had been normal except that an unusual amount of gas had been passed by rectum, there had been no mucus or blood. There had been no urinary symptoms or weight loss.

The past history was irrelevant except for pneumonia in childhood and a tonsillectomy as a young man. The family history revealed that the patient's mother had died of diabetes, and his grandmother, of cancer.

Physical examination disclosed a well nourished patient in no acute distress. The lower abdomen was slightly protuberant. A large, hard, nodular tumor extended upward in the midline from the pelvis to the area of the umbilicus. It was quite fixed in position and seemed to be adherent to the

abdominal wall. Some portions of the mass were slightly tender. Rectal examination was negative. The heart and lungs were normal.

The temperature was 98.6°F, the pulse 86, and the respirations 20. The blood pressure was 138 systolic, 80 diastolic.

Examination of the blood showed a red-cell count of 4,280,000, with a hemoglobin of 13 gm per 100 cc, and a white-cell count of 18,300, with 82 per cent mature neutrophils, 7 per cent young neutrophils and 11 per cent lymphocytes. The urine was normal except for a + test for albumin in one specimen. The nonprotein nitrogen was 27 mg and the serum protein 6.9 gm per 100 cc. The chloride was 94 milliequiv per liter. A stool specimen was brown and gave a negative guaiac reaction. Routine x-ray films of the chest were negative.

Roentgenographically, the kidneys appeared normal in size and position, and intravenous dye was promptly excreted by both kidneys. There was some distention of the right ureter and to a lesser extent of the left midureter, and there was delay in passage of the dye at the level of the sacrum (Fig. 1). The bladder shadow was compressed superiorly by what appeared to be an ill defined midline mass filling the basin of the pelvis. In the lateral view the right ureter appeared displaced anteriorly. There was a small calcified lymph node in the midabdomen. Visualized bones showed no evidence of intrinsic disease. There was spina bifida of the fifth lumbar vertebra without displacement. An attempted examination of the colon showed the sigmoid loop to be displaced downward and compressed toward the left, and barium could not be found beyond that point. It was stated that the films showed no definite evidence of intrinsic disease of the colon.

On the fourth hospital day proctoscopy revealed a sharp posterior angulation 16 cm from the anus that stopped the progress of the instrument. The mucosa was normal, and there was no evidence of ulceration, bleeding or intrinsic tumor. Cystoscopy was attempted, the compression of the bladder from without prevented sufficient distention to enable its mucosa to be visualized.

Except for slight daily elevations of temperature to 99.5°F, there was no change in the patient's condition. On the sixth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. GRANTLEY W. TAYLOR: May we see the x-ray films?

DR. JAMES R. LINGLEY: The margins of the mass are not well defined on the film, but the presence of a mass may be inferred from the evidence of marked pressure on the superior margin of the bladder, with flattening of the bladder shadow, and from the evidence of obstruction of both ureters. In the lateral view one ureter, in addition to being

Taylor's, nor did we take into consideration so many points. We differed when we came to the final analysis and swung in favor of tumor instead of appendiceal abscess, thinking that it probably was a retroperitoneal sarcoma. The only x-ray examination that we did not make was a small-bowel series. At that time we could not visualize a primary lesion of the small bowel that would cause so much difficulty without intestinal obstruction. In retrospect, we should have considered the special tumor of the small bowel that is characterized by distended bowel and not by obstruction.

When we opened the abdomen the first thing visible was massive edema anterior to the peritoneum. Within the peritoneal cavity there was a greatly dilated, perforated loop of ileum. There was a large abscess walled off by the sigmoid. There was a sharp demarcation between normal small bowel and the tumor area, the latter was about 60 cm long. There were also huge lymph nodes in the mesentery, some being as large as 3 cm in diameter. When we saw the gross specimen we were fairly sure of the diagnosis of lymphoma. While the pathologist was examining the tumor, we went ahead with resection of the small bowel and anastomosis.

DR MALLORY: Frozen section of the tumor showed obvious neoplastic disease, which we thought was lymphomatous. That was confirmed by the sections of fixed tissue. Both the bowel wall and the mesentery were diffusely invaded by tumor composed almost entirely of immature lymphocytes, and we classified the lesion as lymphoblastic lymphoma.

Were you able to verify whether or not the retroperitoneal tissues were involved, Dr Welch?

DR WELCH: We could not tell because of the tremendous amount of edema.

DR MALLORY: It had extended so far back into the mesentery that I think it probable that they were.

DR WALTER BAUER: Was this a lymphoblastic type of lymphoma arising in the small intestine?

DR MALLORY: I cannot say whether it arose in the small intestine and invaded the mesentery secondarily, or whether it was in the mesenteric lymph nodes and involved the small bowel.

DR BAUER: And there was never more interference of bowel habit than that mentioned in the record?

DR MALLORY: In lymphoblastoma I have seen 12 to 50 cm of small bowel thickened to the appearance and almost the stiffness of a rubber hose, with no intestinal symptoms.

DR BAUER: Is there a type of lymphoblastoma that is confined to the small intestine and may be cured by resection? If so, what type is it?

DR MALLORY: Any one of the types. We have seen isolated lymphomatous tumors with prolonged

cures after resection in the stomach, the small bowel and the large bowel.

DR BAUER: Have the cures lasted five to twenty years?

DR MALLORY: I am sure that I have seen cures as long as ten years. Beyond that I do not want to say.

DR BAUER: Is that equally true with any of the lymphomatous tumors, the reticulum-cell, the lymphocytic or the lymphoblastic type?

DR MALLORY: One probably has a better chance with a reticulum-cell sarcoma, but I have seen such cures with several types.

DR BENJAMIN CASTLEMAN: Several years ago Dr Gall* reported a series of such cases that had been observed here.

DR TAYLOR: I should like to ask Dr Welch if the mass was primarily inflammatory or whether it chiefly consisted of tumor.

DR WELCH: It was practically all an inflammatory mass.

CASE 32522

PRESENTATION OF CASE

A sixty-two-year-old housewife entered the hospital because of persistent drainage from a cecostomy.

About five years before admission the patient first began having attacks of abdominal pain in the left lower quadrant. These lasted a day or two and were accompanied by a feeling of tenesmus and by loose stools. Between attacks there was no discomfort. The stools gradually became smaller in size but never contained blood and were never black. About fifteen weeks before admission, during an unusually severe attack of pain, the left side of the abdomen was found to be swollen. At that time an operation was performed. The only available details were that an incision had been made in the left lower quadrant, and that a cecostomy had been performed. After the operation the patient was too weak to do more than sit up in a chair for a part of each day. The cecostomy functioned well. Subsequently, a small amount of fecal matter and some mucus were passed by rectum, but never any blood. There had been a weight loss of 13 to 15 pounds in the two months preceding admission. Except for occasional pain on motion of the knees and elbows and slight exertional dyspnea, there were no complaints.

Physical examination showed a moderately obese woman. The abdomen was slightly distended. There was a well healed incision in the left lower quadrant. There was a functioning cecostomy whose mucosa was widely everted. Vaginal examination revealed a normal cervix and a uterus whose fundus was barely palpable in normal position.

process, except the elevation of the white-cell count and the slight rise of the temperature to 99.5°F in the hospital

So we move on to tumors. The only thing we can be grateful for in an otherwise confusing picture is that this patient was not a woman and that we do not have to consider the female genital tumors. It is bad enough as it is. The x-ray evidence regarding the location of the tumor is complicating in the sense that one ureter was pushed forward, suggesting a retroperitoneal origin for the mass. On the other hand, the sigmoid colon seemed to be knuckled backward when palpation was attempted, suggesting an intra-abdominal mass flexing the colon backward. It is hard to see how a retroperitoneal mass would do that to the colon.

From here on it becomes a matter of guessing what kinds of pelvic tumors occur in patients who are practically asymptomatic. We always fall back on the retroperitoneal fibrosarcoma as an explanation for many tumors, and that does not do much more than characterize the histology. We know little about the process, which is a rather frequent finding in a large hospital such as this, I suppose we have a number of them each year that are called retroperitoneal fibrosarcoma. As a rule, when such tumors achieve the size of the one in this case, there is evidence of vascular or lymphatic blockage, as well as a suggestion of associated edema of one extremity and evidence of stasis in the lymphatic or venous return. That is perhaps because the tumor not only causes pressure on the vessels but may actually invade them and propagate in them as a growing tumor thrombus.

A tumor that is frequently seen in this location is the chordoma — another tumor that we do not know a great deal about. As a rule, I believe that all such cases show some evidence of bone destruction because of their locus of origin. They are slow in their progress, and it seems likely that a chordoma that had achieved the size of the tumor in this case would have been observed for many years rather than a brief time. Dermoid cysts that originate in this part of the body are sometimes practically asymptomatic, they are usually symmetrical and smoothly outlined, and the nodular character of the tumor in this case argues against dermoid, unless secondary malignant degeneration had occurred.

Tumors of the lymphoblastic series are usually multiple, sometimes there is a large single tumor, which may appear as a retroperitoneal mass. The negative x-ray findings justify us in ruling out some of the other things that occur to one asked to define the cause of a pelvic tumor. Sometimes, ectopic kidneys, which are infected or otherwise, may become quite large, causing a great deal of trouble for the patient. Bone tumors and chondrosarcoma often reach enormous size and may be located in this region. The primary tumors of the bowel

rarely develop to this extent, and certainly without bowel symptoms they are practically unheard of. Consequently, this tumor must have occurred in tissues that are found in this general region, having no association with any specific organ, if neoplasm is to be regarded as accounting for this patient's symptoms.

Could neoplasm account for the elevation of the white-cell count and temperature? I think that in certain circumstances it could, but the white-cell count was rather high and the young neutrophils suggest that an active inflammatory process was going on somewhere. One neoplasm that I did not allude to, — and I swing back to the appendix again, — is a carcinoid, which may involve the appendix and may become a tumor of significant size, although I have never heard of any carcinoid nearly approaching this one in extent. If I must commit myself, I think that the diagnosis is more probably appendiceal abscess, with a mass around it, than a primary pelvic neoplasm. I base that statement partly on the rapid development, partly on the fact that there was not much in the way of pressure obstruction of the circulatory apparatus of the lower extremities and partly on the specific character of the tumor as described on palpation, since it was much higher in the pelvis than a great many of the tumors to which I have referred. They usually occupy the true pelvis, not the pelvic canal, and are palpable on rectal examination, whereas this tumor was well up and above that, although in the x-ray film it appears to descend fairly low.

A PHYSICIAN: Could the right ureter have been drawn forward rather than pushed out by the mass?

DR TAYLOR: I should think that it could.

DR ROLF LUFT*: In Sweden, years ago, a nurse in a hospital had a large tumor mass in the pelvis that was described as Symmer's disease and that originated in the retroperitoneal lymph nodes.

DR TRACY B MALLORY: Symmer's disease is usually called giant follicular lymphoma in this country.

CLINICAL DIAGNOSES

Sarcoma compressing rectosigmoid, bladder and ureters

Hydronephrosis

DR TAYLOR'S DIAGNOSIS

Appendiceal abscess

ANATOMICAL DIAGNOSIS

Lymphoblastic lymphoma of small bowel

PATHOLOGICAL DISCUSSION

DR CLAUDE E. WELCH: The differential diagnosis on the surgical service was not so thorough as Dr

*Of Stockholm, Sweden.

Taylor's, nor did we take into consideration so many points. We differed when we came to the final analysis and swung in favor of tumor instead of appendiceal abscess, thinking that it probably was a retroperitoneal sarcoma. The only x-ray examination that we did not make was a small-bowel series. At that time we could not visualize a primary lesion of the small bowel that would cause so much difficulty without intestinal obstruction. CASE 32522

PRESENTATION OF CASE

A sixty-two-year-old housewife entered the hospital because of persistent drainage from a cecostomy.

About five years before admission the patient first began having attacks of abdominal pain in the left lower quadrant. These lasted a day or two and were accompanied by a feeling of tenesmus and by loose stools. Between attacks there was no discomfort. The stools gradually became smaller in size but never contained blood and were never black. About fifteen weeks before admission, during an unusually severe attack of pain, the left side of the abdomen was found to be swollen. At that time an operation was performed. The only available details were that an incision had been made in the left lower quadrant, and that a cecostomy had been performed. After the operation the patient was too weak to do more than sit up in a chair for a part of each day. The cecostomy functioned well. Subsequently, a small amount of fecal matter and some mucus were passed by rectum, but never any blood. There had been a weight loss of 13 to 15 pounds in the two months preceding admission. Except for occasional pain on motion of the knees and elbows and slight exertional dyspnea, there were no complaints.

Physical examination showed a moderately obese woman. The abdomen was slightly distended. There was a well healed incision in the left lower quadrant. There was a functioning cecostomy whose mucosa was widely everted. Vaginal examination revealed a normal cervix and a uterus whose fundus was barely palpable in normal position.

There was induration high in the left vault. On rectal examination there appeared to be a mass fixed high to the lateral pelvic wall on the left that did not involve the rectal mucosa. Proctoscopy for a distance of 15 cm showed a normal mucosa. Further progress of the proctoscope was stopped by angulation of the bowel.

Examination of the blood revealed a hemoglobin of 12.4 gm per 100 cc and a white-cell count of 10,200, with 69 per cent neutrophils. The urine gave a + test for albumin, and rare granular casts, 2 red cells and 50 white cells per high-power field were found in the sediment. Barium filled the rectum and distal sigmoid readily. In the mid-sigmoid there was an area of constant narrowing, extending for a distance of about 8 cm (Fig 1), in one portion there appeared to be an absence of the mucosa in a small area, but the remainder of the mucosa looked normal. There was an indefinite

FIGURE 1 Plain Film of Abdomen following a Barium Enema

suggestion of a shelf defect distally and of rounded, filling defects in the lower portion of the lesion.

An operation was performed on the sixth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. WALTER GARREY: It might be instructive to comment briefly about the history and physical findings before we look at the x-ray films. The patient was a sixty-two-year-old woman who for five years had had brief attacks of pain in the left

lower quadrant lasting a day or two, with a feeling of tenesmus and the passage of loose stools. This certainly suggests a recurring inflammatory process in the bowel. Then the patient gave evidence of a gradually increasing degree of chronic, low, large-bowel obstruction — she was definite that the stools had become smaller in size. She had never noticed any blood, although, of course, she may have overlooked it. She had a severe attack of pain and was operated on; apparently, the lesion found was such that the surgeon decided merely to relieve the large-bowel obstruction by doing a cecostomy but did not defunction the bowel with a colostomy. Four months later she was admitted to this hospital, where a mass was found high up in the left pelvis or low in the left lower abdomen. She had a slight degree of anemia and claimed to have lost a little weight. I suppose that the urine was a voided specimen, if so, the white-cell count means little.

May we see the x-ray films?

DR. JAMES R. LINGLEY: This area in the colon, just above the midsigmoid, shows a definite narrowing. No diverticula are visible, and on the inferior margin of the bowel there appear to be round defects. I cannot be too sure of the mucosa in that film, but I think that there is definite evidence of masses in the bowel wall.

DR. GARREY: But there is sufficient filling of the rest of the colon, so that if there had been diverticula farther up the colon they would have shown?

DR. LINGLEY: I think that they would have shown.

DR. GARREY: Is this an annular lesion?

DR. LINGLEY: No, I think that it involves chiefly the lower margin of the bowel and that there is intact mucosa above.

DR. GARREY: Is there a definite ulcer at this spot?

DR. LINGLEY: The fluoroscopist described an ulcer. I cannot be certain from the films.

DR. GARREY: This history could be explained by an inflammatory process because of the recurring attacks for a long time. Far and away the most frequent of all these is a diverticulitis of the sigmoid. The midsigmoid is the likeliest location for diverticulitis, and the chronic obstructing form of diverticulitis easily gives an 8-cm cylindrical obstructing lesion with a normal mucosal pattern, the obstruction being due to a woody-hard, inflammatory reaction in the walls of the bowel. The fact that no blood was noted fits perfectly well with diverticulitis. In the different series of cases of diverticulitis reported, blood has been found in from 6 to 30 per cent. One expects to find blood in cases of carcinoma — even if the patient has not noted it, it is usually found on chemical testing. We have no information whether such tests were done. In over 90 per cent of cases that have diverticulitis in the midsigmoid one or more diverticula are found elsewhere in the colon. None were found in this case, despite fairly good filling. The fact that the obstruction produced by this lesion did not subside

after a cecostomy is no contraindication to the diagnosis of chronic obstructing diverticulitis. In the first place, the bowel was not defunctioned, and many cases on record go for even twelve months with little relief in the inflammatory thickening of the bowel after cecostomy.

What other conditions should we consider? There was an unusual case, seen in this hospital a few years ago and discussed at one of these conferences by Dr McKittrick,¹ of endometriosis involving the sigmoid in a woman past the menopause, but the area of endometriosis and narrowing of the sigmoid was small. With this 8-cm obstruction, or nearly complete obstruction, intussusception of that area is certainly a possibility but a rare and most unusual eventuality.

Could this have been a tuberculous inflammatory lesion? I think that the size and the lack of a large ulcer, as well as the location in the left rather than in the right colon, are against that diagnosis.

Could this have been any form of benign tumor? Such tumors are extremely rare in the colon. Lipomas occur but certainly do not give an 8-cm-long cylindrical type of obstruction. I do not believe that this was a lipoma.

Could the obstruction have been due to something extrinsic to the colon and involving it secondarily? It is possible that cancer of the ovary invaded the sigmoid, but after such a long period, I should expect the patient to have had ascites or signs of dissemination rather than a localized process in the bowel itself.

Another possibility is that, over this long period, some premalignant lesion, such as an adenomatous polyp, was present and that eventually a slowly growing neoplasm developed and invaded the bowel, infiltrating upward in the mucosa, so that part of the mucosal pattern was visible and yet there was some ulceration. I think that that is a good possibility. We are not told whether any tests for blood were made on the stools.

DR TRACY B MALLORY: There is no record of any tests on the stools.

DR GARREY: Could this have been a diverticulitis of the chronic obstructing type, accounting for the history of recurring episodes, with the subsequent development of a carcinoma of the sigmoid, so that there was a double diagnosis? That is possible, and it is interesting that in a series of 40 cases recently reported by Dr Young,² 2 such examples of double lesions were not correctly diagnosed either by x-ray or other studies beforehand. In these exercises, however, it is safer to make one diagnosis than two. Since we are told that there were nodular filling defects in the bowel and an area in which there was

normal mucosa and still another area in which there was ulceration, I shall call this carcinoma, but I think that diverticulitis could perfectly well explain the entire picture.

DR ARTHUR W ALLEN: Dr Garrey has covered this situation exceedingly well. I should like to emphasize one of his last statements. I was afraid that he was not going to mention the diagnosis of carcinoma of the sigmoid, with coincident diverticulitis. That is a fairly frequent finding. Every series of reported cases of diverticulitis or diverticulosis of the sigmoid includes a certain number of such cases. There is a good deal of disagreement concerning the significance of bleeding in the differential diagnosis. Dr Harvey Stone is sure that bleeding can occur from diverticulitis alone. Dr Vernon David, on the other hand, states that with bleeding in a case of diverticulitis of the sigmoid one must assume that carcinoma is present. Both are right to a certain extent. It may interest Dr Garrey to know that the surgeon who first explored this patient and did the cecostomy made the diagnosis of carcinoma, in the acute stage such a diagnosis is frequent. It is difficult to tell by palpation or exploration whether the lesion is inflammatory or neoplastic. We thought that this woman had cancer, but we were wrong. It is only fair to say that we were influenced to some extent by the x-ray finding of the mucosal defects and so forth. It could well have been carcinoma on the basis of the history, in spite of the diverticulitis, as Dr Garrey has pointed out.

CLINICAL DIAGNOSIS

Carcinoma of sigmoid

DR GARREY'S DIAGNOSIS

Carcinoma of sigmoid, superimposed on diverticulitis

ANATOMICAL DIAGNOSIS

Diverticulitis of sigmoid

PATHOLOGICAL DISCUSSION

DR MALLORY: The resected specimen showed a localized area of diverticulitis, with a chronic inflammatory process in the bowel wall accounting for the contraction of the bowel lumen. There were numerous diverticula, all solidly plugged with fecaliths, which explains why the barium did not fill them. There was no evidence of neoplasm.

HAPPY NEW YEAR

CHRISTMAS and New Year, as was suggested on this page last week, travel well together. They are as companionable as Damon and Pythias, as Troilus and Cressida, as ham and eggs, as inseparable in our minds as David and Goliath or as a pick and its shovel. They are more than that: they are almost, although not quite, identical images that have been carelessly imposed on each other. There they are, as like as two peas, but the edges are a little blurred.

They could well have been identical if our old time astronomers had been able to calculate a little more closely, for they both mark the turning of the season, only both are a little late — an almost human failing. It is the Christian Church that attached the religious significance to the pagan festival that is

now Christmas. The New Year, too, has its pious resolutions.

Perhaps it is just as well that Christmas and New Year are a week apart, from a practical point of view. Some heads would hardly be equal to eggnog in the morning and wassail in the afternoon. The present juxtaposition, moreover, without exact identification, like the blurred image, gives us what we really want in midwinter — not simply a holiday, too intense, but a holiday season.

The idea of the Happy New Year, as a greeting, is a good one. No one has really expected, during the last five thousand years or so since civilization began, that the impending year would really be a happy one, and it is surprising how often so many of us have been agreeably disappointed. There has always been someone on every street corner waiting for the world to fall apart, and as a rule most of these, too, have had to turn their grudging footsteps homeward.

Our prediction is that the coming year will bring a number of industrial and international crises, a certain amount of snow and rain and some fair weather and a good deal of hollering by all concerned. At its end we shall find ourselves in port with a few loose rivets, and continue making gloomy forecasts for 1948.

And so, with considerable assurance, we wish all our readers — a select group — our usual Happy New Year!

SYPHILIS AND PENICILLIN

MANY reports have been published indicating the response of syphilis to penicillin therapy. Physicians in general have been quick to adopt this new medicinal agent, and the laity has developed an enthusiasm about its use in syphilis and other diseases that may require some curbing. It is well, therefore, to review with care some of the problems arising in the course of penicillin therapy, such as is done elsewhere in this issue of the *Journal*. Problems arise in connection with the penicillin-resistant case and in matters of relapse, reinfection and reactions. Public-health aspects, including the question of the returning veteran and marriage, are topics of concern in connection with penicillin.

therapy These and other matters must be carefully considered, especially in the light of the gradually increased dosage of penicillin that is being recommended from time to time following careful studies of treated cases Some of these patients did not receive enough penicillin to cure their syphilis and have relapsed or will relapse

The matter of relapse is of special significance In the group of clinics sponsored by the National Research Council and the United States Public Health Service the cumulative percentage failure at the end of eleven months after treatment varied from 15 per cent with a dosage of 2,400,000 units of penicillin to 62 per cent with one of 600,000 units ¹ About 10 per cent of these failures were actually due to reinfection, but the rest were relapses Various treatment schedules were used in the different co-operating clinics, and in general it can be said that there were fewer failures when both arsenic and bismuth were used in combination with the penicillin.

Another complication has been added by the changing character of commercial penicillin ² Various fractions of penicillin have been found and designated G, X, F and K Penicillin K is relatively inefficacious, since it is rapidly destroyed in the body, this assumes significance because of the fact that certain commercial penicillins have recently shown an increasing content of penicillin K It is also not known as yet whether increasing purification of penicillin removes some of the substances that have great therapeutic activity

As a result of reviewing these cases in the various co-operating clinics it has been suggested that for seronegative primary syphilis the minimum dose of the at-present-available penicillin should be not less than 3,600,000 units, given intramuscularly in doses of 40,000 to 60,000 units at two-hour or three-hour intervals For seropositive and early secondary syphilis a dose of not less than 5,400,000 units is recommended If a relapse occurs, arsenic and bismuth should also be given when the course of penicillin is repeated Penicillin by mouth is not advocated Thus, the treatment of syphilis by penicillin has repeatedly been modified as further study of treated cases has progressed

Emphasis is placed on the fact that the present recommendations are only tentative and are subject to revision as the results of treatment are fur-

ther studied The eventual value of penicillin in syphilis is still uncertain, and its ultimate status will not be established for several years to come To be sure that syphilis has been successfully treated by any new procedure requires a long period of observation, measured in terms of years, not months Every physician thus has a particular responsibility for the careful follow-up, serologic and clinical, over a period of years of every penicillin-treated case of syphilis that he sees, whether the penicillin was received in civilian life or during military service

GROUP DONATIONS TO THE MASSACHU-
SETTS BLOOD DONOR PROGRAM

Many social and fraternal organizations are obtaining the benefits of the services and protection offered by the Massachusetts Blood Donor Program by making group donations when the Mobile Unit visits their community By having at least 10 per cent of the total membership of the organization donate to the program, every member in the entire group becomes eligible to receive whole blood, plasma or fractions when needed

Details of the plan for group participation are simple Any organization desiring to donate in a body should communicate with its local Red Cross chapter, expressing a willingness to take part in the program Arrangements for the registration of and appointments for donors can be worked out jointly by group directors and the registration committee in the local chapter

The quota of one donor for each ten members is only temporary and will be adjusted from time to time as the needs of the various organizations change If it is discovered that a quota of 10 per cent does not provide enough blood to meet the requirements of a particular group, the quota will be increased On the other hand, if there is a comparatively small demand from any group, its quota will be accordingly reduced

MOBILE-UNIT VISITS

The Mobile Unit of the Massachusetts Blood Donor Program will make the following visits during the latter half of January

Physicians referring new patients to clinics should get in touch with the district health officer to make appointments

MISCELLANY

HUNDREDTH ANNIVERSARY OF A M A

The American Medical Association is going to celebrate its centennial in Atlantic City on June 9-13, 1947, and elaborate plans are being made for this celebration. Only fellows and invited guests are eligible to attend. Membership in a state society is the primary qualification for fellowship in the Association. Fellowship dues and subscription to the *Journal of the American Medical Association* are both included in one annual payment of \$8.00, which is the cost of the periodical to subscribers who are not fellows.

Anyone who is not a fellow and plans to attend the Atlantic City session, which will be a milestone in medical history, can save himself considerable time and confusion when registering, if he will write now to the American Medical Association, 535 North Dearborn Street, Chicago 10, asking if he is eligible to become a fellow.

NOTE

The following appointments to the teaching staff of Harvard Medical School were recently announced: Henry Freeman Allen, of Boston (A B Harvard University 1939, M D Harvard University 1943), fellow in ophthalmic research, Albert Cislér Biegel, of Denver, Colorado (A B University of Colorado 1941, M D Harvard University 1944), fellow in ophthalmic research, David Lukens Coffin, of Boston (V M D University of Pennsylvania School of Veterinary Medicine 1938), research fellow in pathology, Leonard Paul Eliel, of San Francisco, California (S B Harvard University 1936, M D Harvard University 1940), research fellow in pediatrics, Kenneth Austin Evelyn, of Montreal, Canada (S B McGill University 1932, M D, C M McGill University 1938), research associate in medicine, Geoffrey Alan Gilbert, of Birmingham, England (M A Emmanuel College, Cambridge 1939, Ph D Emmanuel College, Cambridge 1943), research fellow in physical chemistry, Avram Goldstein, of New York City (A B Harvard University 1940, M D Harvard University 1943), assistant in pharmacology, John Harold Hanks, of Newton Center (S B Allegheny College 1928, Ph D Yale University 1931), lecturer on bacteriology and immunology, Harper Keith Hellems, of Lewisburg, West Virginia (M D University of Virginia 1943), research fellow in medicine, Elliott Samuel Hurwitt, of Brookville, Pennsylvania (A B Harvard University 1933, M D Harvard University 1937), research fellow in pathology, Robert Kaye, of Philadelphia, Pennsylvania (A B Johns Hopkins University 1939, M D Johns Hopkins University Medical School 1943), assistant in pediatrics, Frederic Koller, of Zurich, Switzerland (A B College of Trogen 1925, M D University of Geneva 1931, Privat-Dozent University of Geneva 1940, associate in medicine, University of Zurich 1944), research fellow in medicine, Evelyn Lenore Oginsky, of Liberty, New York (A B Cornell University 1938, S M University of Chicago 1939, Ph D University of Maryland 1946), research fellow in bacteriology and immunology, Francis Thomas Garnet Prunty, of London, England (M A University of Cambridge 1935, M D University of Cambridge 1944), research

fellow in medicine, Henrik Seyffarth, of Oslo, Norway (M D University of Oslo 1941), research fellow in neurology, William McLean Wallace, of Hyde Park (A B University of Pennsylvania 1934, M D University of Pennsylvania 1938), assistant in pediatrics, Stanley Moore Wyman, of Cambridge (A B Harvard University 1935, M D Harvard University 1939), assistant in radiology, and Leona Zacharias, of Belmont (A B Barnard College 1927, A M Columbia University 1928, Ph D Columbia University 1937), instructor in ophthalmic research.

BOOK REVIEWS

One Hundred Years of Gynaecology, 1800-1900. A comprehensive review of the specialty during its greatest century, with summaries and case reports of all diseases pertaining to women. By James V Ricci, M D. 4th, cloth, 651 pp. Philadelphia: The Blakiston Company, 1945. \$8.50.

This monumental work is a complement, sequel and conclusion to the distinguished author's previously published *Genealogy of Gynaecology*, which summarized the first thirty-eight hundred years of the history of the specialty. The present volume, both a historical document and a reference book, encompasses the gynecologic literature of the nineteenth century, the greatest of its periods. This literature is not merely immense—it is gigantic. The author has accomplished his colossal objective triumphantly and has produced not a bibliographic catalogue but an integrated story of the development of gynecology to its present status. "Dr Ricci's zeal and industry," says Dr Claude Heaton in his introduction, "have crystallized in a work which will for many years to come be the most complete source book on the literature pertinent to the history of gynaecology." The volume concludes with a fragment "Memoirs in Gynaecology" from Dr Henry Clarke Coe, who was to have contributed a chapter on gynecologic trends since 1870.

Fractures and Orthopaedic Surgery for Nurses and Masseurs. By Arthur Naylor, Ch M, M B, M Sc, F R C S (Eng), F R C S (Edin). With a foreword by Ernest Finch, M D, M S (Lond), F R C S (Eng). 8th, cloth, 288 pp., with 243 illustrations. Baltimore: The Williams and Wilkins Company, 1945. \$5.00.

Anyone who attempts to write a textbook for nurses finds the task of selection of material most difficult: a little knowledge is a dangerous thing, and for this reason, discussions must not be too detailed but must be complete enough that intelligent nursing care can be given. In this book the author has given a satisfactory exposition of fractures and their treatment; this is the best section of the volume. The chapter on orthopedic apparatus is well written and profusely illustrated. The other sections merely catalogue a number of conditions that the orthopedic surgeon treats. Discussion of these conditions is inadequate for a nursing textbook on orthopedic surgery. This book should be particularly helpful to the nurses assigned to the outpatient or inpatient fracture service of a hospital.

Clinical Traumatic Surgery. By John J Moorhead, M D, D Sc. 8th, cloth, 747 pp., with 500 illustrations. Philadelphia: W B Saunders Company, 1945. \$10.00.

This volume is based on the author's experience of over forty years with the surgery of trauma as medical director of the New York City Transit System and consulting surgeon to numerous New York hospitals. It is written frankly in the first person singular, since "the average reader seeks the opinion of the writer," and therefore contains almost no references to the literature. Safe and simple methods of treatment are emphasized throughout, and the book contains much common sense. The discussion of ruptured intervertebral disk is particularly good. The author's opinion, however, is often considerably at variance with generally accepted standard practice and the experience of others. For example, few surgeons would agree that irrigation of fresh open wounds with alcoholic iodine solution should be recommended as a first-aid measure, or that chromic catgut is satisfactory for closure of the skin after the open reduction of fractures. Nowhere in the chapters on shock

and burns are hematocrit or blood-protein determinations mentioned. For the treatment of contusions the external application of soapsuds is advised and no mention is made of cold and compression. Tracheotomy rather than bronchoscopy is recommended for the removal of foreign bodies from the bronchi. The pages on thrombosis and embolism contain no discussion of heparin, dicoumarol or venous ligation.

Although the book will be of interest to others working in the same field, it cannot be recommended for teaching or as a clinical guide for house officers and residents.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Men Under Stress. By Roy R. Grinker, M.D., and John P. Spiegel, M.D. 8°, cloth, 484 pp. Philadelphia: The Blakiston Company, 1945. \$5.00.

This study on war neuroses is based on the authors' experience in working with combat soldiers overseas in an active theater of operation and with returnees hospitalized for rehabilitation.

The Eternal Ones of the Dream. A psychoanalytic interpretation of Australian myth and ritual. By Géza Róheim, Ph.D. 8°, cloth, 270 pp. New York: International Universities Press, 1945. \$4.50.

Dr Róheim, in this monograph, attempts to apply the most recent developments in psychoanalytic theory to the latest available anthropologic data on the natives of Australia, who are among the most primitive human beings still living in the world. The author investigates the origin of myth, particularly the relation of myth to history and ritual, symbolism and nature mythology. He evolves an entirely new theory on circumcision and discusses extensively the interrelation of dreams, day dreams and historical traditions with myths and rituals.

An Introduction to Medical Science. By William Boyd, M.D., M.R.C.P. (Edin.), F.R.C.P. (Lond.), professor of pathology and bacteriology, University of Toronto. Third edition, thoroughly revised. 8°, cloth, 366 pp., with 125 illustrations. Philadelphia: Lea and Febiger, 1945. \$3.50.

This standard manual for nurses has been revised, and the size has been increased by eight pages. A new chapter has been added on the principles of treatment, dealing with such general matters as rest, the sulfonamides, penicillin, immunotherapy, organotherapy and physiotherapy. New material, including the Rh factor, the relation of sex hormones to cancer of the prostate and disseminated sclerosis, has been added, and the chapter on vitamins has been brought up to date. The newer nomenclature of bacteria has been used. The material is well organized. The book is well printed on good paper, and should prove valuable, not only to nurses but also to other professional medical workers and to medical librarians who have used of a concise manual on medicine.

Studies in Biophysics. The critical temperature of serum (56°C). By Lecomte du Nouÿ, D.Sc., director of the Laboratory of Molecular Serology, University of Paris. 8°, cloth, 185 pp., with 89 illustrations. New York: Reinhold Publishing Corporation, 1945. \$3.50.

This monograph is based on a large amount of experimental work, in which a number of new facts have been brought to light. These facts explain the fundamental problems relating to the mechanism of immunologic reaction and also disclose new problems as yet unsolved. The author has formulated a new hypothesis of a serum molecularly dispersed, comprising albumin, globulins, lipoids and so forth, in a true solution, either in a state of more or less

gradual combinations or free, in contradistinction to the hypothesis of colloidal serum. The author concludes that alexinic activity is a property belonging to the protido-lipoidic complexes, which are molecularly dispersed and which constitute the serum, and not to a separate body. He calls attention to twelve distinct physical phenomena occurring in serum when heated to around 56°C, and concludes that there are profound modifications in the structure of the proteins and of the lipo-protidic complex at around 55 to 56°C. This same temperature brings about the destruction of alexin, and therefore the author concludes that the disappearance of alexin is related to the structural clinical modification determined by heat in a serum molecule as a whole. This monograph should be in all medical-school libraries and reference and bacteriologic collections.

Textbook of Obstetrics. Designed for the use of students and practitioners. By Henricus J. Stander, M.D., professor of obstetrics and gynecology, Cornell University Medical College, obstetrician and gynecologist-in-chief, New York Hospital, and director, Lying-In Hospital, New York City. Stander's third revision. 8°, cloth, 1277 pp., with 739 illustrations. New York: D. Appleton-Century Company, Incorporated, 1945. \$10.00.

This new edition of Dr Stander's textbook, designed for students and practitioners, has been thoroughly revised and brought up to date. This work represents the ninth edition of *Williams Obstetrics*, first published in 1902, but since it embodies the teaching and practice of Dr Stander, the title has been changed. This standard work is recommended for all medical libraries and all physicians practicing obstetrics.

A Textbook of Surgery. Compiled from lectures and other writings of members of the Surgical Department of the Harvard Medical School. By John Homans, M.D. With a special bibliographic index and with 530 illustrations by Willard C. Shepard and others. 8°, cloth, 1278 pp. Springfield, Illinois: Charles C. Thomas, 1945. \$8.00.

This sixth edition of an outstanding work on surgery, first published in 1931, has been thoroughly revised, despite the fact that the text pagination is practically unaltered. Much older and out-of-date material has been deleted and over 188 pages of new material have been added. New surgical developments based on war experience have been incorporated throughout the text. The historical approach to the various surgical subjects has been retained, and a bibliographic, historical index of sixty-eight pages is appended to the text. A comprehensive subject index concludes the volume. This work should be in the collections of all those interested in surgery, as well as in all medical libraries.

Studies from the Rockefeller Institute for Medical Research. Reprints. 4°, paper. Vol 127, 605 pp., 1945. Vol 128, 613 pp., 1946. New York: The Rockefeller Institute for Medical Research.

These two volumes contain the results of investigations conducted in the Rockefeller Institute and elsewhere under its grants and originally published in various serials and here brought together for convenient reference. Each volume has an index of authors and subjects.

The Physiological Basis of Medical Practice. A University of Toronto text in applied physiology. By Charles H. Best, C.B.E., M.A., M.D., D.Sc. (Lond.), F.R.S. and F.R.C.P. (Can.), professor and head, Department of Physiology, and director, Banting-Best Department of Medical Research, University of Toronto, and Norman B. Taylor, V.D., M.D., F.R.S. (Can.), F.R.C.S. (Edin.), F.R.C.P. (Can.), M.R.C.S. (Eng.) and L.R.C.P. (Lond.), professor of physiology, University of Toronto. Fourth edition. 4°, cloth, 1169 pp., with 497 illustrations. Baltimore: The Williams and Wilkins Company, 1945. \$10.00.

This fourth edition of a standard textbook is published in a new two-column format that necessitated an entire re-setting of the type. The majority of the illustrations have been reduced to one-column width, and a number of figures have been added and others redrawn. The work has been revised by the addition of new material, and some old mate-

Cornell University 1938, S.M. University of Chicago 1939, Ph.D. University of Maryland 1946), research fellow in bacteriology and immunology; Francis Thomas Garnet Prunty, of London, England (M.A. University of Cambridge 1935, M.D. University of Cambridge 1944), research

fellow in medicine, Henrik Seyffarth, of Oslo, Norway (M.D. University of Oslo 1941), research fellow in neurology; William McLean Wallace, of Hyde Park (A.B. University of Pennsylvania 1934, M.D. University of Pennsylvania 1938), assistant in pediatrics; Stanley Moore Wyman, of Cambridge (A.B. Harvard University 1935, M.D. Harvard University 1939), assistant in radiology; and Leona Zacharias, of Belmont (A.B. Barnard College 1927, A.M. Columbia University 1928, Ph.D. Columbia University 1937), instructor in ophthalmic research.

BOOK REVIEWS

One Hundred Years of Gynaecology, 1800-1900. A comprehensive review of the specialty during its greatest century, with summaries and case reports of all diseases pertaining to women. By James V. Ricci, M.D. 4°, cloth, 651 pp. Philadelphia: The Blakiston Company, 1945. \$8.50.

This monumental work is a complement, sequel and conclusion to the distinguished author's previously published *Genealogy of Gynaecology*, which summarized the first thirty-eight hundred years of the history of the specialty. The present volume, both a historical document and a reference book, encompasses the gynecologic literature of the nineteenth century, the greatest of its periods. This literature is not merely immense—it is gigantic. The author has accomplished his colossal objective triumphantly and has produced not a bibliographic catalogue but an integrated story of the development of gynecology to its present status. "Dr. Ricci's zeal and industry," says Dr. Claude Heaton in his introduction, "have crystallized in a work which will for many years to come be the most complete source book on the literature pertinent to the history of gynaecology." The volume concludes with a fragment "Memoirs in Gynaecology" from Dr. Henry Clarke Coe, who was to have contributed a chapter on gynecologic trends since 1870.

Fractures and Orthopaedic Surgery for Nurses and Masseuses. By Arthur Naylor, Ch.M., M.B., M.Sc., F.R.C.S. (Eng.), F.R.C.S. (Edin.). With a foreword by Ernest Finch, M.D., M.S. (Lond.), F.R.C.S. (Eng.). 8°, cloth, 288 pp., with 243 illustrations. Baltimore: The Williams and Wilkins Company, 1945. \$5.00.

Anyone who attempts to write a textbook for nurses finds the task of selection of material most difficult. A little knowledge is a dangerous thing, and for this reason, discussions must not be too detailed but must be complete enough that intelligent nursing care can be given. In this book the author has given a satisfactory exposition of fractures and their treatment; this is the best section of the volume. The chapter on orthopedic apparatus is well written and profusely illustrated. The other sections merely catalogue a number of conditions that the orthopedic surgeon treats. Discussion of these conditions is inadequate for a nursing textbook on orthopedic surgery. This book should be particularly helpful to the nurses assigned to the outpatient or inpatient fracture service of a hospital.

Clinical Traumatic Surgery. By John J. Moorhead, M.D., D.Sc. 8°, cloth, 747 pp., with 500 illustrations. Philadelphia: W.B. Saunders Company, 1945. \$10.00.

This volume is based on the author's experience of over forty years with the surgery of trauma as medical director of the New York City Transit System and consulting surgeon to numerous New York hospitals. It is written frankly in the first person singular, since "the average reader seeks the opinion of the writer," and therefore contains almost no references to the literature. Safe and simple methods of treatment are emphasized throughout, and the book contains much common sense. The discussion of ruptured intervertebral disk is particularly good. The author's opinion, however, is often considerably at variance with generally accepted standard practice and the experience of others. For example, few surgeons would agree that irrigation of fresh open wounds with alcoholic iodine solution should be recommended as a first-aid measure, or that chromic catgut is satisfactory for closure of the skin after the open reduction of fractures. Nowhere in the chapters on shock

rial has been deleted. Fifty-eight pages of references to the various chapters are appended to the text. A large, comprehensive index concludes the volume. The text is printed in two sizes of type, the smaller of which is rather difficult to read, but is used for less important material. This work should prove valuable to all practicing physicians for reference.

Classic Descriptions of Disease With biographical sketches of the authors. By Ralph H. Major, M.D., professor of medicine, University of Kansas School of Medicine. Third edition. 4°, cloth, 679 pp., with 158 illustrations. Springfield, Illinois: Charles C. Thomas, 1945. \$6.50.

This third edition of a standard work in the field of the history of medicine, first published in 1932, has been revised by the addition of several new selections, and a bibliography has been added for the first time. Dr. Major has made two hundred and eighty-seven selections from the original accounts of one hundred and ninety-five physicians of all countries whose contributions and discoveries in the field of clinical medicine have been outstanding. These accounts are either the first known, one of the earliest or one of the most interesting accounts in question. The whole field of clinical medicine is covered from the time of the Papyrus Ebers, one thousand years before Hippocrates, to modern times. The work is divided into ten subject sections which are preceded by a historical summary and often by short biographic sketches. The original accounts have been translated into English wherever necessary, and the text is illustrated with carefully chosen portraits and facsimiles of titles and texts and drawings of apparatus. The book should be in all medical libraries, as well as in the collections of physicians interested in the history of medicine.

Psychiatry in Modern Warfare. By Edward A. Strecker, M.D., Litt D., LL.D., professor of psychiatry and chairman of the department, University of Pennsylvania School of Medicine, and Kenneth E. Appel, Ph.D., M.D., Sc.D., assistant professor of psychiatry and chief of clinic, University of Pennsylvania School of Medicine, and lecturer in psychiatry, School of Neuropsychiatry, United States Naval Hospital, Philadelphia. 12°, cloth, 88 pp. New York: The Macmillan Company, 1945. \$1.50.

The modern aspects of psychiatry as applied to the disasters associated with war are reviewed. The text is sound, and the book can be recommended. Although brief, it contains much that is pertinent to present conditions.

Diseases of the Nervous System. By F. M. R. Walshe, O.B.E., M.D., D.Sc., F.R.C.P. (Lond.), D.Sc. (hon.), physician in charge of the Neurological Department, University College Hospital, London, physician to the National Hospital for Nervous Diseases, Queen Square, neurologist to the Hospital for Tropical Diseases, London, and to the Seamen's Hospital, Greenwich, and fellow of University College, London. Fourth edition. 8°, cloth, 360 pp., with 51 illustrations. Baltimore: The Williams and Wilkins Company, 1945. \$4.50.

This popular small book, designed for practitioners and students, has passed into its fourth edition during the war years, a tribute to the soundness of the author's contribution. Some new material has been added, but in general the book remains as it was when first issued—a sound résumé of the subject, with emphasis on the clinical aspects of neurology. The author has been reasonably successful in keeping the book up to date, but the task is not an easy one and some modern advances are not given full recognition. Conservatism, however, is the keynote of the book and perhaps its most valuable asset. This volume, as a brief text of value to the clinician, can be given unqualified approval.

Take It Easy. The art of conquering your nerves. By Arthur G. Mathews. 8°, cloth, 239 pp., with 26 symbolical illustrations. New York: Sheridan House, 1945. \$2.98.

The author has attempted to express in lay terms the present conception of neuroses and their treatment. In addition to the text he has used simple diagrams. In general his book is sound, but oversimplification detracts from its value. It is not a book that should receive unqualified recommendation.

NOTICES

JOSEPH H. PRATT DIAGNOSTIC HOSPITAL

Bennet Street, Boston

Lecture Hall, 9-10 a.m.

MEDICAL CONFERENCE PROGRAM

Friday, January 3 — Pulmonary Disease in Modern Industry
Dr. Harriet Hardy

Wednesday, January 8 — Motion Picture: Energy Release from Food

Friday, January 10 — Sterility. Dr. Somers Sturgis

Wednesday, January 15 — Rheumatic Fever. Dr. T. Duckett Jones

Friday, January 17 — Changes in Biologicals and in Human Reactions. Dr. Ralph E. Wheeler

Wednesday, January 22 — Pediatric Clinicopathological Conference. Drs. James M. Baty and H. E. MacMahon

Friday, January 24 — Parenteral Fluid Therapy for the Starving Dehydrated Patient, Infant and Adult. Dr. Allan Butler

Wednesday, January 29 — Nasal Resistance Inhaler: A new method for the prevention and treatment of aerotitis media and aerotitis sinusitis. Dr. H. F. Sternstein

Friday, January 31 — Gout. Dr. Elmer C. Bartels

On Tuesday and Thursday mornings, Dr. S. J. Thibaut will give medical clinics on hospital cases. On Saturday mornings, clinics will be given by Dr. William Dameshek. Medical rounds are conducted each weekday except Saturdays by members of the staff from 12:00 to 1:00 in the Lecture Hall.

All exercises are open to the medical profession.

GREATER BOSTON MEDICAL SOCIETY

A meeting of the Greater Boston Medical Society will be held in the auditorium of the Beth Israel Hospital on Tuesday, January 7, at 8:15 p.m. Dr. Leo M. Davidoff, of the Montefiore Hospital, New York City, will talk on "Recent Advances in Brain Surgery."

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, January 2, at 7:15 p.m., in the classroom of the Nurses' Residence. Dr. Edward L. Young will speak on "Gall Bladder Disease Associated with Duodenal Ulcer and Hypertension." Dr. Dorothy K. Scheidell will be chairman.

NATIONAL CONFERENCE ON MEDICAL SERVICE

The twentieth annual meeting of the National Conference on Medical Service will be held at the Palmer House, Chicago, Illinois, on February 9. Registration will commence at 9:00 a.m., and the program will include discussions in the fields of national affairs, economics and medical education. All physicians are invited to attend; there is no registration fee. Dr. Cleon A. Nafe, of Indianapolis, is president of the conference, and Dr. Creighton Barker, of New Haven, Connecticut, is secretary.
